alloys.^[35] In that study, the influence of not only overheating temperature but also cooling rates (0.3–1000 K/s) on microstructure and properties has been analyzed. Figure 12 shows a contour plot of the DAS parameter (μm) of the Al–7% Si alloy overheated to different temperatures. It is seen that higher overheating usually leads to smaller DAS, although there are clear anomalies in the range of 700–750°C and after 830°C (where double decrease in the DAS at low cooling rates ~ 1 K/s may be obtained by increasing overheating). High cooling rates of 1000 K/s have smaller influence on DAS irrespective of overheating.^[35]

The hardness of the Al–7% Si alloy is shown in Fig. 13. The dependence of hardness on overheating is now similar for all cooling rates studied. There are peaks of hardness at 700°C and a “valley” between 740°C and 800°C, where the lowest hardness values have been found at any cooling rate. One may calculate that the target hardness level

Fig. 12 DAS (μm) in the Al–7% Si alloy overheated to different temperatures and crystallized from these temperatures at different rates

Fig. 13 Hardness (HRB) in the Al-7% Si alloy overheated to different temperatures and crystallized from these temperatures at different rates

of 45–50 HRB of this alloy may be achieved at cooling rates $< 1 \text{ K/s}$ after overheating at either $700 \pm 10^\circ\text{C}$ or $860\text{--}880^\circ\text{C}$. If the overheating temperature is $740\text{--}760^\circ\text{C}$, then this hardness level may only be achieved at cooling rates $> 1000 \text{ K/s}$. Detailed X-ray diffraction analysis carried out in Ref. [35], has confirmed metastable X- and η -phase formation. Thus, the isothermal crystallization diagram for the Al-7% Si alloy may be drawn as shown in Fig. 14. This indicative diagram is valid for the alloy that was overheated to 900°C . If the overheating temperature is different, a

Fig. 14 Schematic of the isothermal crystallization of the Al-7% Si alloy overheated to 900°C

new crystallization diagram may be constructed, and the optimal temperature regimes could be determined.

Since the determination of crystallization fields and metastable phases is very time-consuming, it is important to develop measurement techniques for faster analysis of the solidification processes. A good choice for that are thermoanalytical techniques. Thermal analysis measurements by differential scanning calorimetry (DSC) were made by authors on the unmodified Al-7% Si, 21.5% Si, and 36% Si alloys^[34] using a Netzsch STA449C “Jupiter” simultaneous thermal analyzer. It allows very precise measurement of the heat flow with a temperature resolution of 0.1°C and mass changes of $\pm 0.1 \text{ mg}$. Specimens of $\sim 100\text{--}200 \text{ mg}$ have been heated, held, and cooled in pure argon with different rates up to 830°C , 900°C (the abovementioned critical temperatures in the metastable Al-Si system), and 1480°C (to destroy possible associates, clusters, or other heritage effects). Thermal effects have been registered at heating and cooling that correspond to both stable and metastable equilibria (Figs 15 and 16). In Fig. 15, the effect of the cooling rate is seen to impact significantly on the metastable peritectic-type reaction, but causes only small oscillations in the onset and peak of the “liquidus” of this alloy. If these changes had been caused by faster cooling rates only, the extrapolation on the zero cooling rate would result in the “stable” liquidus of the Al-21.5% Si alloy ($\sim 723^\circ\text{C}$), which is obviously not the case (the extrapolation of both peak and onset temperatures gives $\sim 680^\circ\text{C}$). The complicated dependence of the metastable peritectic

Fig. 15 Thermal effects in the Al-21.5% Si alloy overheated to 1480°C and cooled at different rates – temperature onset point at liquidus (◆), peak temperature for liquidus (■), metastable peritectic (▲), stable liquidus border (-----)

line (Fig. 15) suggests that such extrapolation is unlikely to be valid, because at lower cooling rates, the system would probably go via a different crystallization route according to another metastable phase diagram.

Figure 16 shows thermal effects in three alloys with different silicon concentrations on heating and cooling. Only hypereutectic alloys have metastable peritectic peaks between “stable” liquidus and eutectic thermal effects.^[34] What is more interesting is that there are reproducible thermal effects, associated with the “phase transformations” in the liquid state, far above the “stable” liquidus line for all the alloys. For hypereutectic alloys, the clear effect at 934–937°C exists at cooling, whereas, for a hypoeutectic alloy (7% Si), it is situated near 680°C. These findings demonstrate the usefulness of the thermal analysis application for studying crystallization phenomena (actually, these methods have been used for this purpose before). Here, the point is in very careful application of known techniques (e.g. activation energy, kinetics, or enthalpy determination with non-isothermal methods) and critical assessment of the results, because data received with different cooling rates may easily reflect different

Fig. 16 Thermal effects in three Al-Si alloys heated at 20K/min to 1480°C and cooled at 10K/min: transformations in the liquid phase (● – heating 20K/min, ■ – cooling 10K/min), eutectic temperature peaks (Δ), metastable peritectic (◆). Lines of the stable Al-Si diagram are also shown for comparison

crystallization processes. In this case, simple comparison of the cooling curves makes very little sense for process optimization.

It has been experimentally confirmed^[19,25] that pouring of the Al-Si melts from temperatures higher and lower than those mentioned above results in different microstructural appearance of silicon and aluminum-rich crystals and, respectively, properties of castings. For example, the alloy Al-21.5% Si-2.5% Cu-2.5% Ni was heated up to 920–940°C (this corresponds to the phase transformation in the liquid phase; Figs. 15 and 16), held there about 15 min and then cooled down to the pouring temperature (810–940°C). As-cast specimens were analyzed for their microstructure and mechanical properties (ultimate tensile strength, fracture toughness, microhardness, hardness). On the basis of more than 1000 specimens, a correlation between basic mechanical properties (UTS and impact energy) and pouring temperature was revealed (Fig. 17). This dependence is not linear and cannot be described by a smooth function either – instead, it has clear peaks and valleys of properties in narrow temperature intervals (10–30°C). The level of properties

Fig. 17 Mechanical properties of the Al-21.5% Si alloy, overheated to 920°C and poured from different temperatures: ● ultimate tensile strength (MPa); ○ – impact energy (J)

(maximal UTS 205 MPa at 940°C, impact energy 3.9 J at 890°C) and their variations leave no doubts about a tight connection between microstructural transformations in the liquid state, metastable phase appearance, and decomposition and the final properties. Thus, “optimal” pouring temperature (taking into account industrial limitations and costs for very high overheating of the melt) of the Al–21.5% Si alloy was in the range of 845–860°C, which corresponds to the second viscosity anomaly in the Al–Si system discussed above.

It is worth noting that these properties have been achieved without any grain refiners, master alloys, or modifiers – only by a simple optimization of the heating schedule. There is also a proof of finer microstructure of the optimally cast alloy in comparison with the non-optimized one (Fig. 18). These two photos present the microstructure of the alloy, which was heated and soaked according to the same temperature program, but was poured from two different temperatures, with the difference being only 12°C. The specimen with finer microstructure had a UTS of 150 MPa, impact energy of 3.3 J, hardness of 100 HB, and excess hexagonal crystal size of 15–30 μm , with the microhardness being 10–12 GPa. Another specimen had lower UTS (< 140 MPa), impact fracture energy (2.65 J), and hardness (90 HB).

With this technique, the new technology of optimization of microstructure and phase composition as well as resulting properties has been developed^[19,33] for alloys of the Al–Si system. Therefore, use of master alloys or modifiers is not always necessary if the temperature and time parameters of the casting process can give the same or even better results with respect to grain sizes and mechanical properties.

CONCLUSIONS

The contents of this chapter may be summarized in the following statements or recommendations, which should be kept in mind for selection of the master alloys and performing the aluminum alloy modification and grain refinement. A good guideline rule tells us that there are no absolute guidelines, but all possible factors should be taken into account:

- Aluminum alloy history (processing, impurities, possible metallurgical heritage, charge composition, i.e. scrap content, etc.).
- Casting technology parameters (heating rate, overheating temperature, soaking time, pouring temperature, and soaking time at this point, crystallization rate at different parts of castings, etc.).
- The results of the microstructural, macrostructural, and physical investigation: are the alloy processing parameters optimal from the point of view of grain size, mechanical properties, foundry defects, etc.? If not, can temperature and time programs be adjusted, and what will the result be in that case?
- When the optimal processing parameters are fixed, the selection of modifying master alloy(s) may be done on the basis of the most desired effect (grain size refinement, DAS decrease, strength and elongation increase, hardness adjustment, etc.).
- The optimal amount of master alloy(s), introduction temperature and time, soaking, mixing, and pouring parameters have to be determined on the basis of target properties of castings. The formation of possible metastable phases and their influence on the morphology and microstructure of the final alloys should be taken

Fig. 18 Microstructure of the Al–21.5% Si alloy, poured from two different temperatures, with the difference being only 12°C. Note large differences in microstructure and silicon crystals

into account. This requires more scientific effort to be applied to the problem before the operational window is set up for the casting process.

ACKNOWLEDGMENTS

The authors would like to thank all their colleagues and contributors who have taken part in this research and have assisted in exciting research to reveal the peculiarities of microstructure formation in aluminum alloys. The part on the thermal analysis studies of metastable phase transformations was also supported by a grant from the Academy of Finland.

The Crystallography of Aluminum and Its Alloys

Philip N.H. Nakashima

Department of Materials Science and Engineering, Monash University, Victoria 3800, Australia

Abstract

This article begins with pure aluminum and a discussion of the form of the crystal structure and different unit cells that can be used to describe it. Measurements of the face-centered cubic lattice parameter and thermal expansion coefficient in pure aluminum are reviewed and parametrizations are given which allow the reader to evaluate them across the full range of temperatures where aluminum is a solid. A new concept called the “vacancy triangle” is introduced and demonstrated as an effective means for determining vacancy concentrations near the melting point of aluminum. The Debye–Waller factor, quantifying the thermal vibration of aluminum atoms in pure aluminum, is reviewed and parametrized over the full range of temperatures where aluminum is a solid. The nature of interatomic bonding and the history of its characterization in pure aluminum are reviewed with the unequivocal conclusion that it is purely tetrahedral in nature. The crystallography of aluminum alloys is then discussed in terms of all of the concepts covered for pure aluminum, using prominent alloy examples. The electron density domain theory of solid-state nucleation and precipitate growth is introduced and discussed as a new means of rationalizing phase transformations in alloys from a crystallographic point of view.

Keywords: Alloys; Crystal structure; Debye–Waller factor; Interatomic bonding; Intermetallic precipitates; Lattice parameters; Nucleation and precipitation; Orientation relationships; Parametrizations; Solid solutions; Thermal expansion coefficient; Unit cells; Electron density domain theory.

INTRODUCTION

When it comes to a discussion of the crystallography of aluminum and its alloys, there is vast scope and a semi-infinite number of perspectives that could be adopted. In this article, a hierarchic approach is chosen. This means that the focus is initially on pure aluminum before its alloys are considered. The hierarchy breaks the crystallographic discussion down into four aspects: (i) the nature of the crystal structure and efficient ways of describing it; (ii) the magnitude of the lattice parameter at any given temperature where aluminum is a solid (and therefore the linear thermal expansion coefficient); (iii) the amplitude of atomic vibrations in the lattice as a function of temperature, again in the range of temperatures where aluminum is a solid; and (iv) the nature of the bonds between the atoms. The hierarchy outlined leads to the determination of interatomic bonding, which is the dominant determinant of all materials properties (with the sole exception of radioactivity which is only nuclear). Interatomic bonding is considered the ultimate level of crystallographic characterization of a crystalline material and the basis that drives all other aspects of the structure.

Only after considering the four aspects of the crystallography of pure aluminum given previously, can a discussion of aluminum alloys proceed. This article examines

these four aspects for pure aluminum and then brings them to bear on a discussion of aluminum alloys via a number of significant and illustrative examples.

THE CRYSTAL STRUCTURE OF PURE ALUMINUM

Aluminum in its pure form has a face-centered cubic (fcc) crystal structure, which is a close-packed arrangement (the densest geometric packing of spheres attainable) with a layer sequence of ABCABCA.... This is illustrated in Fig. 1.

In close-packed structures (both hexagonal close-packed, hcp, and fcc), there are always twice as many tetrahedral interstices as there are octahedral ones. This is evident for an elemental fcc structure, such as aluminum, illustrated in Fig. 1C where the primitive rhombohedral cell, which equivalently describes the structure but contains only a single atom, is drawn within the fcc unit cell. This primitive cell is composed of two tetrahedral interstices sandwiching an octahedral one and because the primitive cell tessellates with periodic repetitions of itself to canonically describe the crystal structure of aluminum, the ratio of tetrahedral to octahedral interstices of 2:1 applies to the bulk.

Fig. 1 The fcc crystal structure of aluminum viewed with [111] pointing up exposes the ABCABCA... stacking of close-packed atoms (A). The atoms in a single unit cell (cell edges shown) have a darker shade. When viewed along the [111] direction (B), the order of packing is revealed by assigning each layer of atoms a different color (blue for A, red for B, and green for C). It is evident from this view that the layers A, B, and C do not line up in the [111] stacking direction. The familiar fcc cell is drawn with a smaller atomic radius so that the atoms are not represented by touching spheres (C). Close-packed structures contain twice as many tetrahedral as octahedral interstices, as shown. The illustrated tessellation is a canonical description of the crystal structure as one octahedral interstice sandwiched by two tetrahedral ones form an ensemble that is the primitive rhombohedral cell. This primitive cell, containing just one atom, is, in fact, the most efficient description of the crystal structure (D). The relationships between lattice parameters for the fcc and primitive cells are also given. This figure was drawn with the aid of the VESTA crystallographic visualization software package^[1]

“Rules of thumb” for a close-packed elemental structure’s ability to accommodate atoms of different elements within its interstices can be established from basic geometric arguments governing each type of interstitial position, as schematically illustrated in Fig. 2. Considering the atoms of the host structure to be close-packed hard spheres allows the size of each interstitial position to be calculated using simple geometry. It turns out that the largest sphere that can be accommodated by an octahedral interstice has a radius of 0.414 times that of the host matrix atom radius in a close-packed structure. For a tetrahedral interstice, the largest sphere that can be accommodated without strain has a radius 0.225 times the radius of the host atoms. If one considers metallic aluminum and its alloys, then there are very few situations in which alloying atoms are located interstitially because they would have to have radii of $\leq 0.593 \text{ \AA}$ to be accommodated in the octahedral interstices and $\leq 0.322 \text{ \AA}$ to be accommodated, without strain, in the tetrahedral interstices.

Considering only neutral atoms, only hydrogen has a sufficiently small covalent radius ($0.37 \text{ \AA}$)^[2] to be accommodated interstitially in aluminum. Oxygen and fluorine atoms, having covalent radii of $0.66 \text{ \AA}$ and $0.64 \text{ \AA}$, respectively,^[2] can be accommodated in the octahedral interstices with considerable strain; however, these elements will form very strong chemical bonds with aluminum atoms, resulting in a change in crystal structure (e.g., the various phases of aluminum oxide).

Diffusion of hydrogen via the interstices in aluminum can result in the formation of aluminum hydrides, which are very detrimental to the integrity of aluminum and its alloys. Thankfully, in most situations, aluminum and its alloys are protected by a passivating oxide layer that effectively blocks, not only further oxidation of the aluminum but also the ability of hydrogen to diffuse into the aluminum. One way in which hydrogen can become a problem is if the protective oxide surface of the aluminum or its alloys is being stripped away at a rate that allows

Fig. 2 Octahedral interstices (A–C) can nominally fit interstitial atoms or ions whose radii are no greater than 0.414 times the radius of the host atoms (F) in close-packed structures, like aluminum. Tetrahedral interstices (A, D, and E) are significantly smaller and can only accommodate atoms or ions with radii no greater than 0.225 times the radius of the host atoms (F) in close-packed structures. Here, the rhombohedral cell of aluminum is shown (A) with interstitial atoms just fitting in the octahedral interstices (red; A–C) and both of the tetrahedral interstices (green; A, D, and E). These radius ratios (F) are geometric “rules of thumb” and do not take chemical bonding effects into account. This figure was drawn with the aid of VESTA^[1]

hydrogen to enter and diffuse through the exposed aluminum lattice. This can occur, for example, during electropolishing of aluminum and its alloys if the temperature of the electropolishing solution is not maintained at a sufficiently low level (e.g., -20°C for HNO_3 /methanol solutions).

Some of the most advanced aluminum alloys contain lithium. Only lithium ions can be accommodated interstitially, having ionic radii of $0.60 \text{ \AA}$, whereas the neutral atoms have radii of $1.35 \text{ \AA}$.^[2] This becomes important when it comes to characterizing aluminum alloys with ionizing radiation (e.g., in transmission electron microscopy). Lithium is relatively easily ionized by high-energy beams of radiation, and this makes lithium highly mobile in aluminum alloys that contain it, due to migration via interstitial pathways. As a result, lithium is particularly difficult to locate in aluminum alloys using electron microscopy and techniques that probe materials with high-energy radiation.

The size of the interstices in aluminum means that almost all alloy solid solutions in aluminum are substitutional, with different elements having different solid solubilities in aluminum. Upon heat treatment of supersaturated aluminum-based solid solutions, phase transformations resulting in the formation of intermetallic precipitates can occur where the precipitates have entirely different crystal structures from the host fcc aluminum matrix.

Although the focus on aluminum alloys is left until the “Crystal Structures of (Some) Aluminum Alloys” section, it will be useful at this point to consider other ways of describing the atomic structure of pure or elemental aluminum. This is done in Fig. 3, the purpose of which is to serve as a handy reference for the structural modeling of intermetallic precipitate phases and the surrounding aluminum matrix in aluminum alloys. Many such phases are to a greater or lesser degree coherent with the aluminum

host matrix along interfacial planes that are not necessarily $\{001\}$ in the fcc cell. For example, the T_1 phase (Al_2CuLi) in aluminum–copper–lithium alloys is hexagonal and forms fully coherent platelets with main facets composed of the basal plane (001), which is coplanar to $\{111\}$ planes in the fcc cell of the aluminum matrix. To model the ensemble structure of matrix/precipitate/matrix, one could either use the fcc cell of the aluminum matrix and substitute $\{111\}$ planes with the T_1 structure, or one could use the trigonal cell defined in Fig. 3D–F to describe the aluminum matrix and then simply replace $\{001\}$ planes in this description with the T_1 structure, coplanar to the T_1 structure’s basal plane of (001). The equivalence of these approaches to modeling this alloy structure may make the use of different descriptions of the aluminum matrix structure seem redundant; however, when it comes to applying such structural models to the analysis of experimental data, the defining frames of reference become vital to the task.

An example is the interpretation of electron diffraction patterns or lattice images using the multislice formalism for describing electron scattering from crystals.^[3] This method requires the material being probed and analyzed to be sliced into its constituent planes of atoms whose normals are parallel to the incident electron beam direction. This requires the two-dimensional periodicity of the crystal structure to be defined perpendicularly to the beam direction so that sampling of the structure within slices can be Fourier transformed as part of the multislice algorithm. This is only practical if the beam and slicing directions are defined as $[001]$ throughout the structure being modeled. In the example of T_1 , this is only possible if the aluminum host matrix is described using a trigonal cell like the one defined in Fig. 3D–F.

Although Figs. 1 and 2 show the rhombohedral primitive cell of aluminum in order to illustrate the geometric

Fig. 3 Four alternate unit cells that will fully describe any fcc metal like aluminum. Each cell is shown in relation to the familiar fcc cell (with atoms in the alternate cell in red and those in the fcc cell but outside the alternate cell in blue) (A, D, G, and J). Each alternate cell is also shown standing alone (atoms in blue) (B, E, H, and K). The alternate cells shown here have axes and cell faces that correspond to the growth axes and planes of many of the precipitate phases encountered in aluminum alloys (see Table 4 and Section “Crystal Structures of (Some) Aluminum Alloys”). Having the full description of the geometric relationships between these alternate cells and the fcc cell (C, F, I, and L) on hand is useful for modeling and analyzing precipitate/matrix interfacial structures in aluminum alloys and for determining the degree of coherence of such interfaces and the amount of strain imparted on the host aluminum matrix by the precipitates. Reference to these geometric relationships is also very useful in the context of simulating electron scattering within aluminum alloys in different directions using the multislice formalism.^[3] This is an important tool for interpreting TEM images and diffraction patterns and TEM is one of the primary techniques for characterizing alloys at the atomic scale. This figure was drawn with the aid of VESTA^[1]

relationship between the constituent atoms in the two types of interstices that exist in the structure of aluminum, Fig. 3 presents four additional cells that are defined in relation to the familiar fcc unit cell (and in one case, the rhombohedral primitive cell): a body-centered tetragonal (bct) cell where c is the longest cell edge (Fig. 3A–C), a trigonal cell (Fig. 3D–F), an orthorhombic cell (Fig. 3G–I), and a tetragonal cell where c is the shortest cell edge (Fig. 3J–L). For each of these alternative cells, their orientation and position with respect to the fcc description of the structure of aluminum is presented by showing the constituent atoms of the new cells in red. In contrast, the atoms that belong only to the fcc cell and that are not common to the fcc cell and the cell being defined are shown in blue (Fig. 3A,D,G,J).

The second frame in the definition of each new cell (Fig. 3B,E,H,K) shows a single unit cell of the new definition with all atoms colored blue. In the case of the orthorhombic cell (Fig. 3H), the two opposing face-centered atoms are also at opposing corners of the primitive rhombohedral cell, so this has been drawn in for further context.

The third frame in each cell definition (Fig. 3C,F,I,L) explicitly states the geometric relationships between each newly defined cell and the fcc unit cell. The lengths of each of the cell edges are given in terms of a_{fcc} , the lattice parameter of the fcc cell, and the angles between cell edges are given explicitly in degrees. The orientation relationships between the edges of the cell being defined and directions in the fcc cell are given next. This is followed by the space group symmetry defining the symmetry-related locations of atoms in each new cell and, in conjunction with the assigned space group, the symmetry-independent atom positions required to locate all of the atoms constituting the new cells.

The unit cells defined in Fig. 3 cover many of the coherent or semicoherent systems of matrix/precipitate/matrix encountered in aluminum alloys. The only variable whose value is not specified in the definitions presented in Fig. 3 is the fcc lattice parameter of aluminum, a_{fcc} . The next section examines the lattice parameter of aluminum and its associated linear thermal expansion coefficient, in sufficient detail to produce an accurate parametrization of both of these physical characteristics as a function of temperature, allowing the user to obtain their values to high accuracy in pure aluminum at any temperature where aluminum is solid (i.e., 0 K–933 K). The value of a_{fcc} at whatever temperature is relevant to a particular experiment is the value that should be substituted into the geometric relationships listed for each cell definition in Fig. 3.

THE LATTICE PARAMETER OF PURE ALUMINUM

Fundamental to the crystallography of any crystalline material is the knowledge of the lattice parameter of the unit cell. For aluminum, the fcc cell is always taken as the frame of reference (so $a = b = c$ and $\alpha = \beta = \gamma = 90^\circ$).

Here, a summary of the literature is presented with a particular focus on experimentally measured lattice parameters for aluminum between 0 K and the melting temperature of 933 K. From more than 300 measurements spanning this temperature range, a function for the lattice parameter with respect to temperature, $a(T)$, has been determined (see Eq. 1). The present parametrization can be used to give the lattice parameter at any temperature that aluminum is a solid. In addition, the self-normalized derivative of this function should give an accurate function for the thermal expansion coefficient of aluminum, $\alpha(T)$. A summary of experimentally measured thermal expansion coefficients for aluminum is also presented in this section.

Measurements of the lattice parameter date back to the 1920s and the early days of X-ray diffraction and crystallography.^[4–6] A large number of measurements of the aluminum lattice parameter have been made since then,^[7–71] using not only powder and single-crystal X-ray diffraction but also electron diffraction.^[54,55] The references provided here may not be exhaustive but are as complete as possible. Appendix A gives a tabular summary of each reference,^[4–71] the temperature at which determinations were made, and the lattice parameter determined at each temperature. Notes about each measurement, where relevant, and sample purity, where available, are supplied in the summary. Prior to the mid-1940s, measurements of lattice parameter were conventionally given in units of kX. The unit, X, was derived from the calcite spacing, thought at the time of its definition to be 1×10^{-13} m. Therefore, units of kX (or 1000X) were taken as equivalent to 10^{-10} m—the unit of length referred to nowadays as the Ångström. However, it was found that the calcite spacing was in error by $\sim 0.2\%$. In 1947, none other than Bragg and Armstrong Wood made the clarifying statement that $1\text{kX} = 1.00202 \text{ Å}$.^[72] Further research settled on the conversion factor of $1\text{kX} = 1.00208 \text{ Å}$.^[73] When summarizing the measurements of $a(T)$ over the past 90+ years, values quoted in kX have been converted to Å using the appropriate conversion factor.

Figure 4 plots all experimental measurements of the aluminum fcc lattice parameter against the temperature of each measurement. The literature includes a number of attempts to extrapolate the low-temperature data to a value of $a(0 \text{ K})$,^[59,63,65] and these are shown as the green points in the graph. The blue line is the best fit to the experimental data (including the $T = 0 \text{ K}$ extrapolated values) of the following function:

$$a(T) = \frac{m}{(n+T)^{14}} \left(\sum_{i=0}^{15} p_i T^i - \sum_{i=0}^{14} q_i T^i \ln(n+T) \right). \quad (1)$$

The optimized parameters for Eq. 1 are listed here to 15 significant figures to prevent rounding errors when evaluating the equation (rounding errors can make this otherwise monotonic function non-monotonic at $T < 20 \text{ K}$):

Fig. 4 A graphical summary of lattice parameter measurements in pure aluminum, from 1925 to the present day.^[4–71] There are 326 independent experimental measurements plotted as red points, ranging from 4.6 to 927 K (just below the melting point of 933 K). Three points are given at 0 K (green), and these were determined by extrapolating low-temperature measurements back to absolute zero.^[59,63,65] All points are graphed with error bars; however, some uncertainties are too small to be resolved in the graph. The blue line represents the function fitted to these experimental data (Eq. 1). The inset expands the graph in the low-temperature range to show how Eq. 1 performs in this region

$$m = 5.46215569838344 \times 10^{-4}, n = 86.0150000000000,$$

$$\begin{aligned} p_0 &= 1.80595722249783 \times 10^{31}, p_1 = 2.96317351342354 \times 10^{30}, p_2 = 2.25855016769900 \times 10^{29}, \\ p_3 &= 1.06004494945302 \times 10^{28}, p_4 = 3.42305759706082 \times 10^{26}, p_5 = 8.04609813573980 \times 10^{24}, \\ p_6 &= 1.41998402393052 \times 10^{23}, p_7 = 1.91189157411850 \times 10^{21}, p_8 = 1.97428843905832 \times 10^{19}, \\ p_9 &= 1.55692828415459 \times 10^{17}, p_{10} = 9.23827056204128 \times 10^{14}, p_{11} = 4.00527886712625 \times 10^{12}, \\ p_{12} &= 1.20273329860717 \times 10^{10}, p_{13} = 2.25714359192389 \times 10^7, p_{14} = 2.06989439078737 \times 10^4, \\ p_{15} &= 1.00000000000000, \end{aligned}$$

$$\begin{aligned} q_0 &= 2.04335860741967 \times 10^{30}, q_1 = 3.32581764853519 \times 10^{29}, q_2 = 2.51326102603950 \times 10^{28}, \\ q_3 &= 1.16875476418741 \times 10^{27}, q_4 = 3.73664547057534 \times 10^{25}, q_5 = 8.68835777614448 \times 10^{23}, \\ q_6 &= 1.51514697020481 \times 10^{22}, q_7 = 2.01313321790028 \times 10^{20}, q_8 = 2.04788881667471 \times 10^{18}, \\ q_9 &= 1.58723386748412 \times 10^{16}, q_{10} = 9.22649460840626 \times 10^{13}, q_{11} = 3.90058588445197 \times 10^{11}, \\ q_{12} &= 1.13369350824041 \times 10^9, q_{13} = 2.02772058226054 \times 10^6, q_{14} = 1.68385961108157 \times 10^3. \end{aligned}$$

Figure 5 compares the present fitted function for $a(T)$ with the seminal models of Wang and Reeber for perfect and real crystals^[74] as applied to aluminum.^[75] The distinction between perfect and real is ignoring and accounting for the presence of vacancies, respectively. These models deviate significantly from the experimental measurements and thus, from the present fit, at low temperatures. In the middle range of temperature, there is an excellent agreement between both models and the present fit, whereas the perfect and real models diverge from each other at higher temperature and bound the present fit. The divergence of the two Wang and Reeber models shows the increasingly significant effect of vacancies on the average lattice parameter in a real crystal, where the concentration of vacancies increases rapidly with temperature as the melting point of aluminum is approached. This becomes even more evident when the linear thermal expansion coefficient, $\alpha(T)$, for aluminum is examined.

The functional form and optimized parameters of Eq. 1 were constrained by the requirement that the self-normalized derivative of Eq. 1 with respect to temperature (resulting in

Eq. 2) must also be the best fit to experimental determinations of the thermal expansion coefficient, $\alpha(T)$, of aluminum. The experimental measurements of $\alpha(T)$ span more than 100 years of research^[15,16,18,20,22,29,42,43,45,49,52,53,59,60,69,76–96] and are plotted in Fig. 6. Specific values and notes from each reference are given in Appendix B. The experimental data are plotted together with $\alpha(T)$ according to the perfect and real crystal models of Wang and Reeber^[74,75] and the function for $\alpha(T)$ determined in the present work:

$$\alpha(T) = \frac{1}{a(T)} \frac{da(T)}{dT} = \frac{\sum_{i=0}^{15} s_i T^i}{(n+T) \left(\sum_{i=0}^{15} p_i T^i - \sum_{i=0}^{14} q_i T^i \ln(n+T) \right)} \quad (2)$$

The optimized parameters for fitting Eq. 2 to the experimental data points are as follows:

Fig. 5 A graphical comparison of the present fitted function of lattice parameter versus temperature, $a(T)$ (Eq. 1 and Fig. 4), with the perfect and real crystal models of aluminum by Wang and Reeber.^[74,75] The low- and high-temperature ranges have been expanded to show the deviations between the present function, $a(T)$, and Wang's and Reeber's models in these ranges. At low temperatures, the perfect and real crystal models of Wang and Reeber agree exactly due to the low equilibrium concentration of vacancies. Nearer the melting point of aluminum, the vacancy concentration becomes large enough to cause the real crystal model of the lattice parameter to be significantly greater than that of the perfect crystal model

Fig. 6 A graphical summary of thermal expansion coefficients for aluminum from 0 to 933 K (the melting temperature). Experimental measurements date from 1907 to the present day.^[15,16,18,20,22,29,42,43,45,49,52,53,59,60,69,76–96] The thermal expansion coefficient as a function of temperature, $\alpha(T)$, as determined by the present review (Eq. 2), is plotted and compared with $\alpha(T)$ as determined by the perfect and real crystal models of Wang and Reeber.^[74,75] The inset expands the low-temperature region of the graph to show the quality of the fit of $\alpha(T)$ determined here with low-temperature measurements. A new concept, the “vacancy triangle,” is drawn into the graph and spans the divergent area at higher temperatures where $\alpha(T)$ determined from changes in lattice parameter differs from $\alpha(T)$ determined by bulk length dilations, the latter being affected by vacancies

$$\begin{aligned}
 s_0 &= 8.55692806695981 \times 10^{18}, s_1 = 1.09556645819752 \times 10^{24}, s_2 = 1.78316852655619 \times 10^{23}, \\
 s_3 &= 2.04804545623587 \times 10^{22}, s_4 = 1.60396172331341 \times 10^{21}, s_5 = 2.36491757661617 \times 10^{20}, \\

 s_9 &= 2.93361641840158 \times 10^{14}, s_{10} = 2.08150841393624 \times 10^{12}, s_{11} = 8.47737173962446 \times 10^9, \\
 s_{12} &= 5.09073073293741 \times 10^7, s_{13} = 3.26718741801178 \times 10^5, s_{14} = -3.93634611081583 \times 10^2, \\
 s_{15} &= 1.00000000000000
 \end{aligned}$$

and parameters n , p_i , and q_i are the same as for Eq. 1. Again, all parameters have been listed to 15 significant figures to avoid problems associated with rounding errors.

The constraint that interdependent Eqs. 1 and 2 simultaneously fit the experimental determinations of $a(T)$ and $\alpha(T)$ from 0 K to near the melting point of 933 K resulted in the large number of terms in both functions to ensure excellent simultaneous fits spanning the whole temperature range where aluminum is a solid. Previous efforts to fit functions to both $a(T)$ and $\alpha(T)$ were based largely on polynomials and were only valid over limited temperature ranges.^[59,63,68,70,77,91,95,96] One particular example by Kroeger

and Swenson,^[96] which represents some of the most rigorous work to date for $\alpha(T)$, fits numerous polynomial functions of varying orders to four separate temperature ranges that in combination go from 0 K to 330 K. In total, 24 parameters are used. In the present fits, 32 independent parameters (given $p_{15} = 1$ for Eq. 1) are required for $a(T)$ from 0 K to 933 K, and an additional 15 independent parameters (given $s_{15} = 1$ for Eq. 2) are required for $\alpha(T)$ from 0 K to 933 K.

The present fit functions for $a(T)$ and $\alpha(T)$ lie between the bounds set by the Wang and Reeber perfect and real crystal models at the high-temperature end of the graphs in Figs. 5 and 6. This can be understood by considering the present fits as averages over the spread in the experimental

determinations spanning the literature, whilst the perfect and real crystal models of Wang and Reeber^[74,75] represent the theoretical upper and lower bounds of such measurements, respectively.

The experimental thermal expansion data shown in the plot of Fig. 6 are compiled from measurements of both $\Delta a/a_0$ and $\Delta L/L_0$. The former ratio is the change in lattice parameter from its value at a particular reference temperature, T_0 , divided by the value of the lattice parameter at that temperature. Measurements of lattice parameter invariably involve a diffraction experiment (usually single crystal^[29,40,45,60,92] or powder X-ray diffraction^[15,16,20,22,29,42,43,49,52,53,59,69,82,84]). The latter ratio comes from measurements of changes in length of a bulk sample of material. The length dilation, ΔL , with changes in temperature relative to a reference temperature, T_0 , can be very accurately measured by any number of techniques. These include interferometry,^[18,53,60,78,81,86,91] capacitance or differential transformer dilatometry,^[40,89,94–96] fixed comparative optical microscopy,^[45,76,77,92] and optical leveraging.^[90] The denominator, L_0 , is simply the absolute length of the bulk sample at the reference temperature. The reference temperature, T_0 , is a temperature at which the vacancy concentration can be considered to have a negligible effect on length dilation with changes in temperature. In other words, $\Delta a/a_0 \equiv \Delta L/L_0$ at T_0 .

Measurements of $\Delta a/a_0$ show what is happening in terms of only the unit cell dimension, whereas measurements of $\Delta L/L_0$ reflect what is happening to the bulk material as a result of changes in cell dimension plus dilation of the bulk caused by the presence of vacancies. This means that the difference between thermal expansion coefficients measured crystallographically and by bulk length dilation is a direct measure of vacancy concentration. By definition,^[40,42,45,53,60,90] the vacancy concentration, C_{vac} , is given by

$$C_{\text{vac}} \approx 3 \left(\frac{\Delta L}{L_0} - \frac{\Delta a}{a_0} \right). \quad (3)$$

Using the approximations that $a \approx a_0$ and $T \approx T_0$ (both accurate to within 2% across the entire temperature range that aluminum is a solid), the thermal expansion coefficient, $\alpha(T)$, can be related to $\Delta a/a_0$ and $\Delta L/L_0$ as follows:

$$\alpha_{\text{min}}(T) = \frac{1}{a} \frac{da}{dT} \approx \frac{1}{a_0} \frac{da}{dT}; \quad \alpha_{\text{max}}(T) = \frac{1}{L} \frac{dL}{dT} \approx \frac{1}{L_0} \frac{dL}{dT}. \quad (4)$$

Here, $\alpha_{\text{min}}(T)$ is essentially the linear thermal expansion coefficient for a perfect crystal, whereas $\alpha_{\text{max}}(T)$ is that for a crystal containing the equilibrium concentration of vacancies at temperature T . It then follows that

$$\int_{T_0}^T \alpha_{\text{min}}(T) dT \approx \frac{1}{a_0} \int_{a_0}^a da = \frac{\Delta a}{a_0}; \quad \int_{T_0}^T \alpha_{\text{max}}(T) dT \approx \frac{1}{L_0} \int_{L_0}^L dL = \frac{\Delta L}{L_0}, \quad (5)$$

and therefore

$$\left(\frac{\Delta L}{L_0} - \frac{\Delta a}{a_0} \right) \approx \int_{T_0}^T \alpha_{\text{max}}(T) dT - \int_{T_0}^T \alpha_{\text{min}}(T) dT. \quad (6)$$

Because each integral is just the area under $\alpha_{\text{max}}(T)$ and $\alpha_{\text{min}}(T)$, respectively, Eq. 6 is equivalent to the area spanned by the spread in experimental determinations of $\alpha(T)$ by measurements of both $\Delta a/a_0$ and $\Delta L/L_0$ as the temperature gets high enough for vacancies to have an appreciable effect on length dilation. The spread in experimental determinations of $\alpha(T)$ is bounded by $\alpha_{\text{max}}(T)$ and $\alpha_{\text{min}}(T)$, and the area is approximately represented in the graph of $\alpha(T)$ (Fig. 6) as the shaded triangle. According to Eqs. 3 and 6, the area of this triangle should be equivalent to one-third of the vacancy concentration at the temperature at which the vertical edge of the triangle is located (927 K in the present summary). The area of the triangle as drawn in Fig. 6 is $\sim 4.46 \times 10^{-4}$, and therefore, $C_{\text{vac}} \approx 1.3 \times 10^{-3}$. The present triangle encompasses almost all of the experimental points and therefore represents an upper bound. Depending on where the left vertex of the triangle is positioned, the area of the triangle can change somewhat, and a lower bound on the area has also been measured. It is 2.7×10^{-4} , which equates to $C_{\text{vac}} \approx 8.1 \times 10^{-4}$. Thus, the vacancy concentration reported using the new “vacancy triangle” estimation method presented here for the first time is $C_{\text{vac}} \approx (1.1 \pm 0.3) \times 10^{-3}$. This is comparable with determinations published previously by individual studies^[40,42,45,53,60,92] as shown in Table 1. The C_{vac} determined from the vacancy triangle in Fig. 6 agrees, within the given margins of error, with all previous determinations of C_{vac} near the melting point of aluminum, with the exception of the determination of Feder and Nowick.^[40] The result reported by Feder and Nowick^[40] is significantly different to all other determinations from the literature summarized here.

The present determination is on the higher side of the range of estimations previously published and can be explained by the fact that the triangle only approximates the region bounded by $\alpha_{\text{max}}(T)$ and $\alpha_{\text{min}}(T)$. A more accurate shape would be a triangle with the top edge replaced by a concave-up arc, which would reduce the enclosed area and, thus, the estimated vacancy concentration. In addition, the triangle is drawn to contain almost all of the experimental measurements of $\alpha(T)$, while the true spread may not be as large.

Vacancies are fundamental crystal defects that have a very strong influence on the diffusion of solutes in alloys. This and the fact that they can act as nucleation sites for precipitate phases and phase transformations mean that vacancies play a pivotal role in the evolution of alloy microstructure along any heat treatment route. Vacancies alone are known, under conducive conditions, to aggregate into nanoscale voids,^[97–104] which can be

Table 1 A comparison of previously published vacancy concentration determinations for aluminum near its melting point with the determination using the “vacancy triangle” method derived in the present work

C_{vac}	T (K)	Reference
$(1.1 \pm 0.3) \times 10^{-3}$	927	Present
3×10^{-4}	933	[40]
$(1.1 \pm 0.2) \times 10^{-3}$	933	[42]
9.4×10^{-4}	933	[45]
$(9 \pm 1) \times 10^{-4}$	933	[53]
9.8×10^{-4}	933	[60]
8.5×10^{-4}	928	[92]

Notes: Previous determinations used measurements of $\Delta L/L_0$ and $\Delta a/a_0$. The vacancy triangle approach is described here in this review for the first time and is a quantitatively useful way of interpreting the spread in the experimental graph of $\alpha(T)$ versus T in Fig. 6 in terms of the vacancy concentration at the temperature bounding the vertical side of the vacancy triangle (927 K in the present experimental summary). Note that the vacancy triangle method gives a vacancy concentration (emphasized in bold in the table) that agrees, within the margins of error, with all previous determinations summarized in the table, with the exception of the result from Ref. [40]. The measurement of Ref. [40] appears to significantly underestimate C_{vac} near the melting point and is also at odds with all other determinations presented in the table.

deleterious to mechanical and electrical properties.^[105–110] On the other hand, voids have great potential in the fabrication of novel electronic, catalytic, and plasmonic materials.^[111–113] Voids have received significant attention over the years,^[97–123] and a very recent paper revisits them in aluminum with new findings about how they evolve by the migration of vacancies through different crystallographic facets.^[123]

The primary focus of this section is, however, on the lattice parameter of aluminum, its dependence on temperature, and the properties that can be derived from it. This section closes with a comparison of the aluminum lattice parameter and linear thermal expansion coefficient obtained from Eqs. 1 and 2 respectively (using the coefficients listed previously), with average experimental values determined from published measurements^[4–71,76–96] at six key temperatures: 0 K, 50 K (the lower limit of Wang’s and Reeber’s models^[74,75]), 273 K (freezing point of water), 298 K (room temperature), 400 K (near the Debye temperature of aluminum^[86,124]), and 923 K (10 K below the melting point of aluminum as measurements at the melting point are not feasible). This is provided in Table 2.

From the comparisons in Table 2, there is little surprise that the present functions for $a(T)$ and $\alpha(T)$ agree with the experiments as they were fitted to them. As discussed previously, the agreement of the present fits with the models of Wang and Reeber^[74,75] is best in the middle temperature range and not as good at low and high temperatures. The perfect crystal model of Wang and Reeber (WRP in the table) ignores the vacancies that are present in significant concentrations at temperatures approaching the melting point, whereas their real crystal model (WRR) does not. The present functions for $a(T)$ and $\alpha(T)$ are flanked by WRP and WRR at high temperatures in both cases because WRP gives a theoretical lower bound for both $a(T)$ and $\alpha(T)$, whereas WRR gives an upper bound and, in principle, the present functions (Eqs. 1 and 2) should give the average of the two models. At any rate, the functions for $a(T)$ and $\alpha(T)$ presented here in Eqs. 1 and 2, respectively, together with the listed optimum fit

Table 2 A comparison of the lattice parameter, $a(T)$, and the linear thermal expansion coefficient, $\alpha(T)$, at six key temperatures (0, 50, 273, 400, 298, and 923 K)

T (K)	$a(T)$ (Å) Experimental	$a(T)$ (Å) WRP	$a(T)$ (Å) WRR	$a(T)$ (Å) (Eq. 1)
0	4.0317 ± 0.0002	—	—	4.0319
50	4.0321 ± 0.0001	4.0327	4.0327	4.0321

298	4.0497 ± 0.0006	4.0498	4.0498	4.0493
400	4.059 ± 0.001	4.0598	4.0598	4.0594
923	4.1237 ± 0.0006	4.1226	4.1252	4.1237
	$\alpha(T) \times 10^6$ Experimental	$\alpha(T) \times 10^6$ WRP	$\alpha(T) \times 10^6$ WRR	$\alpha(T) \times 10^6$ (Eq. 2)
0	0.000	—	—	0.000
50	3.7 ± 0.4	3.969	3.962	3.795
273	22.7 ± 0.4	22.53	22.63	22.80
298	23.2 ± 0.2	23.19	23.20	23.40
400	25.1 ± 0.2	25.23	25.16	25.17
923	36 ± 1	33.93	39.80	36.10

Notes: The values of $a(T)$ and $\alpha(T)$ obtained from Eqs. 1 and 2 (shown in bold), respectively, using the given parameters are compared to the average of the experimentally measured values for $a(T)$ and $\alpha(T)$ from the literature^[4–71,76–96] reviewed here and Wang’s and Reeber’s perfect (WRP) and real (WRR) crystal models^[74,75] (also plotted in Figs. 5 and 6).

parameters, are intended to provide a useful resource for researchers requiring information about the lattice parameter or linear thermal expansion coefficient of aluminum at any temperature where aluminum is a solid.

THE DEBYE–WALLER FACTOR OF ELEMENTAL ALUMINUM

In the pursuit of a fundamental understanding of materials properties, all routes lead back to the bonding electron density that is the dominant determinant of almost all materials properties (except radioactivity). Aluminum is no exception. Although the bonding electron density of aluminum is the subject of the next section, its determination depends on three fundamental pieces of *a priori* information. As can be gleaned from the layout of this article, the first is the type of unit cell and the location of the atoms within it, and the second is the dimension of the unit cell (or the lattice parameter). The third is the thermal vibration amplitude of the aluminum atoms. This is quantified by the Debye–Waller factor (DWF).^[124,125]

Figure 7 illustrates an ambiguity in time-averaged electron distributions between atoms, namely: which fraction is due to bonding and how much is due to the thermal motions of the atoms? When viewed in connection with Eqs. 7 and 8, the origin of this ambiguity becomes obvious. The starting point is the fact that any periodic object can be described by a Fourier sum. In the case of a crystal, this sum is

$$\rho(\mathbf{r}) = \frac{\sum_{\mathbf{g}} F_{\mathbf{g}} e^{-2\pi i \mathbf{g} \cdot \mathbf{r}}}{V_{\text{cell}}}, \quad (7)$$

where $\rho(\mathbf{r})$ is the electron density at a position in the unit cell with real space vector $\mathbf{r}$. The sum is over all reciprocal lattice vectors, $\mathbf{g}$, and $F_{\mathbf{g}}$ are the Fourier coefficients of the crystal electron density, known as structure factors. V_{cell} is the volume of the unit cell. The structure factors, $F_{\mathbf{g}}$, are determined according to the following equation:

$$F_{\mathbf{g}} = \sum_j \underbrace{f_j(s)}_{\text{static electron distribution}} \underbrace{e^{-B_j s^2}}_{\text{temperature factor}} \quad (8)$$

where the sum is over all atoms in the unit cell and $f_j(s)$ is the atomic form factor for the j^{th} atom at position $\mathbf{r}_j$ in the unit cell, and $s = (\sin\theta_{\mathbf{g}})/\lambda$ for the set of atomic planes with reciprocal lattice vector $\mathbf{g}$, having Miller indices h, k , and l . $\theta_{\mathbf{g}}$ is the Bragg angle for this set of planes, corresponding to the wavelength, λ , of the radiation being diffracted from the planes with structure factor $F_{\mathbf{g}}$. The first component of the equation essentially quantifies the $T = 0$ K electron distribution contribution to the structure factor. The second exponential in Eq. 8 is referred to as the temperature factor, where B_j is the DWF of the j^{th} atom at a particular temperature.

The temperature factor “smears” the electron distribution from its static form to give its time-averaged dynamic form due to the thermal vibration of the constituent atoms. Therefore, if the DWF is not accurately known, then one has no way of knowing the relative contributions of the static and dynamic components to the structure factor, and therefore, it is impossible to accurately determine the true bonding electron distribution. This is illustrated in Fig. 7.

In theory, the DWF deals only with the thermal vibrations of atoms. In practice, crystal defects can serve to “smear” measurements of structure factors in a similar way that the thermal vibrations do. As a result, the International Union of Crystallography has introduced the term “atomic displacement parameters”, which acknowledges that static as well as dynamic (thermal) displacements of atoms from their modeled sites result in a reduction of the scattering power of planes of atoms in a particular direction, quantified by the associated structure factor.

Given that many crystalline materials can be annealed to remove most displacive crystal defects (especially true for metals), the remaining obstacle to the accurate experimental determination of bonding electron densities is accurate knowledge of the DWFs of the constituent atoms at the temperature of the experiments. In the present section, a summary of $B(T)$ (the DWF as a function of temperature) is presented for elemental aluminum, as determined from previous literature.^[126–155] The aim, again,

Fig. 7 Two pairs of bonded atoms of the same element are compared (A and B) with clearly more electron density between the atoms in the second case (B). Is the larger electron density between the atoms in case B due to stronger bonding or larger thermal motion than in case A? Without specific knowledge of the DWFs for each case, this cannot be answered. See Eq. 8

is to provide a resource for conveniently obtaining $B(T)$ for aluminum over the range of temperatures where aluminum is a solid.

Figure 8 plots experimental measurements of the DWF against temperature where the data points were obtained from an extensive survey of the literature.^[126–155] For specific values, their sources and some notes associated with each source, see Appendix C. Analytical derivations of the DWF for the general case where anharmonic vibrations are also considered have concluded that the temperature dependence of $B(T)$ in its most general form for fcc structures should be a cubic function of temperature:^[141,147,151,156,157]

$$B(T) = m + nT + pT^2 + qT^3. \quad (9)$$

This function is fitted to the experimental data points in Fig. 8, giving the blue line in the graph and the optimized parameters:

$$m = 0.18488, n = 1.3926 \times 10^{-3}, p = 3.1939 \times 10^{-6} \text{ and } q = -4.6582 \times 10^{-10}.$$

The fit of Eq. 9 to the experimental data with these coefficient values cannot be improved by adding higher orders as Peng et al. have done in their parametrization of $B(T)$ for many elements,^[158–160] which involve a quartic function of temperature.

Fig. 8 A graphical summary of published experimental measurements of the DWF for aluminum spanning the range of temperatures where aluminum is a solid.^[126–155] The blue line is the best fit of Eq. 9 to the experimental data points (red dots with error bars), yielding the optimized parameters listed in the text. This should be used as a reference for $B(T)$ in analyses which require the DWF as input without measuring it in an associated experiment

Equation 9 with the optimized parameters listed (plotted in Fig. 8) predicts a significant zero-point energy with $B(0 \text{ K}) = 0.18 \pm 0.04 \text{ Å}^2$. Sternemann et al.^[155] report $B(15 \text{ K}) = 0.15 \text{ Å}^2$, which is lower than other measurements at 4 K and 20 K,^[131] but more in alignment with the low-temperature powder X-ray diffraction work of Rantavuori and Tanninen,^[149] which was aimed at measuring very accurate structure factors in aluminum as part of a bonding electron density study. Their study gave $B(80 \text{ K}) = 0.22 \text{ Å}^2$. This value is substantially lower than other measurements at $T = 80 \text{ K}$, which have a very narrow spread about a central value of 0.33 Å^2 .^[126,131,137–139]

It might well be argued that the alignment between the precision measurements of Sternemann et al.^[155] and Rantavuori and Tanninen^[149] is suggestive of their accuracy. On the other hand, it could equally be argued that the weight of measurements suggests $B(80 \text{ K})$ is nearer to 0.33 Å^2 than to 0.22 Å^2 , calling into question the lower zero-point energy that Sternemann et al.^[155] and Rantavuori and Tanninen^[149] would suggest. It is also possible that higher concentrations of crystal imperfections may have affected the measurements of $B(4 \text{ K})$, $B(20 \text{ K})$, and $B(80 \text{ K})$ in many of the cases, leading to elevated values. Regardless, the present fit effectively averages out these differences and, as a result, has a significant level of uncertainty associated with its prediction of $B(0 \text{ K})$.

Theoretical work in the derivation of $B(T)$ from interatomic forces, calculated from a variety of *ab initio* potentials and electron gas screening functions, has yielded some varied results for aluminum.^[148,156,157,161–166] These are plotted, together with the parametrization of $B(T)$ by Gao and Peng^[159,160] and the fit of Eq. 9 to the experimental results^[126–155] in Fig. 9. Only Killean's nearest neighbor central force pair interaction model^[148] is a good fit to $B(T)$ determined by experiments.

The other models plotted in Fig. 9 are derived from (i) the Ashcroft pseudopotential with a Vashishta-Singwi screening function (AVS),^[157,161] (ii) the Ashcroft pseudopotential with a Hubbard screening function (AH),^[157,163,164] (iii) a Harrison-modified point ion pseudopotential with a Hubbard-Sham screening function (HHS),^[157,163,164] and (iv) a Morse potential (Morse).^[157,162] Three separate models (numbered in the graph) are derived from each of these potentials: (i) quasi-harmonic, (ii) quasi-harmonic plus low-order perturbation terms as per Maradudin and Flinn,^[156,157] and (iii) fully inclusive of all anharmonic contributions via a Green's function approach.^[157,165,166]

Gao and Peng's parametrization^[159,160] was based on the phonon density of states determinations of Gilat and Nicklow,^[138] which relied on the measurements of Stedman and Nilsson.^[137] This parametrization has been a useful reference where input of the DWF has been required in analyses of experimental data and where it has not been measured *in situ*. At $T = 293 \text{ K}$, the Gao and Peng parametrization^[159,160] gives $B(293 \text{ K}) = 0.82 \text{ Å}^2$, whereas

Fig. 9 A comparison of the present function for $B(T)$ (see Eq. 9 with the optimized parameters listed in the text) with different theoretical models for $B(T)$ ^[148,156,157,161–166] and the parametrization by Gao and Peng.^[159,160] The present function for $B(T)$ is the best fit to the experimental data surveyed in this work^[126–155] and is the thickest solid line in the graph (red). The nearest neighbor central force pair interaction model of Killean^[148] (solid bright blue line) is in closest agreement with experiments across the range of temperatures where aluminum is a solid. On the other hand, the parametrization by Gao and Peng^[159,160] does not fit the experimental measurements well at all (solid black line). All of the other theoretical determinations of $B(T)$ are plotted with dashed lines, and the abbreviations with which they are tagged identify the potentials and screening functions used to derive the corresponding $B(T)$ curves (described in the text)

the present function and optimized parameters give $B(293 \text{ K}) = 0.86 \pm 0.04 \text{ Å}^2$. Gao and Peng's parametrization is in best agreement with the present function for $B(T)$ in the range of 100–300 K. Therefore, analyses of near-room-temperature data will not be strongly affected by the choice of $B(T)$ function, whether it be that of Gao and Peng^[159,160] or the present function. However, in regions of higher or lower temperatures, Gao and Peng's parametrization deviates significantly from the present function for $B(T)$ and therefore also from the experimental measurements of the DWF. The deviation is especially large at higher temperatures, where use of the present function for $B(T)$ is strongly advised.

Eq. 9 with its optimized parameters, given above, represents the summary of all of the published experimental measurements of $B(T)$ ^[126–155] and is useful as a simple reference tool when $B(T)$ is required as input and is not measured *in situ*. The next section deals with the determination of the bonding electron distribution in aluminum and, as illustrated by Eq. 8 and Fig. 7, a reliable knowledge of $B(T)$ at the temperature at which structure factors are measured is vital to the accurate determination of bonding. This is true for any material.

THE BONDING ELECTRON DISTRIBUTION IN ALUMINUM

Aluminum has been the focus of considerable charge density research for almost a century.^[126,127,129,130,133,140,144,149,152,154,167–186] What makes this metal so interesting is that it closely approximates an ideal Drude metal,^[187] which is commonly described as a lattice of “cations immersed in a sea of delocalised electrons.” This is in fact the crude description applied to metals in general at high school and undergraduate levels in order to describe metallic bonding and the general properties of malleability, ductility, and thermal, electrical, and acoustic conduction that it gives rise to.^[188] Although this description is a gross approximation, aluminum fits it remarkably well and better than most other metals. Aluminum is one of nature's best approximants to a “free-electron gas” or “jellium” and, as a consequence, is an excellent thermal conductor, is highly malleable, is one of the best-known electrical conductors, and is the most efficient reflector of visible radiation (a direct result of the oscillation of its nearly free valence electrons, i.e., plasmons).

The bonding electron distribution in materials is key to all of their properties (with the exception of radioactivity,

which is entirely nuclear). Therefore, to gain a fundamental understanding of the properties of aluminum, one must closely examine the nature of metallic bonding between the atoms in it.

Experimental measurements of the electron density in aluminum were largely confined to X-ray diffraction experiments^[126,127,129,130,133,140,144,149,167–170,172] from powders or single crystals. Some higher precision results from electron diffraction were obtained by the critical voltage method,^[152,173,174] and the highest precision measurements to date were presented in a recent study using quantitative convergent-beam electron diffraction (QCBED).^[175]

Conventional single-crystal and powder X-ray diffraction techniques variably suffer from errors caused by extinction, which originates from the single scattering approximation (or kinematic approximation) made in the analysis of the diffracted intensities.^[189] A number of approaches^[190–193] have been developed and applied to correct for the multiple scattering (or dynamical diffraction) that inevitably occurs in crystals with small unit cells and relatively high degrees of crystal perfection; however, these approaches all involve significantly limiting approximations. Experiments seeking dynamical diffraction data and applying a full dynamical scattering analysis eliminate the concept of extinction and, in turn, should result in more accurate measurements. Pendellösung experiments with X-rays and single crystals have been attempted with aluminum and are included in this review.^[172] The problem with this method is that it is difficult to obtain perfect single crystals of the sizes needed for such X-ray experiments, especially when it comes to metals because metallic bonding supports crystal defects very readily, which is associated with the property of ductility and malleability—the defining characteristics of metals. Crystal imperfections cannot be avoided in the volumes of metal needed to perform these dynamical X-ray diffraction experiments, which in turn leads to error in the measurement of structure factors by these techniques.

Although X-rays are scattered by the total electron density in a crystal, electrons, being charged, are scattered by the crystal potential. Potential and electron density are related (via a simple electrostatic relationship called the Mott formula^[194]) in such a way that makes electron diffraction more sensitive to bonding than to the rest of the electron density. In addition, electrons, due to their charge, interact with matter about 1,000 to 10,000 times more strongly than X-rays and can be focused into subnanometer probes with electromagnetic lenses. This combination means that convergent-beam electron diffraction (CBED) is able to probe volumes of material with $<10^5$ atoms. This is about 10^{10} times smaller than is possible with conventional X-ray diffraction techniques, thereby allowing defect-free regions of crystal to be probed selectively by CBED in electron microscopes.

CBED gave rise to the critical voltage method for measuring bonding-sensitive structure factors, and several studies using this technique were carried out for aluminum^[152,173,174] The problem with this approach is that

the range of structure factors that can be measured is extremely limited. The smaller the structure factor magnitude, the higher the electron energy required to reach the point at which there is a change in contrast in the CBED pattern that acts as the indicator in the method. The electron energy at which this occurs is used to determine the magnitude of the relevant structure factor(s). The electron energy is a direct product of the accelerating voltage in an electron microscope and higher accelerating voltages, and thus, higher electron energies require larger and larger electron guns to accelerate the electrons to the required energy. This means that the critical voltage method has a limited range of applicability because it is impractical to make electron guns huge enough to measure more than just the strongest two or three structure factors in a material. In aluminum, the practical limit is just the two strongest structure factors, F_{111} and F_{200} . This was insufficient to unequivocally determine the bonding electron density in aluminum as it was long thought that bonding information also resides in the next structure factor, F_{220} , that is inaccessible by the critical voltage method.

QCBED has emerged in the past two to three decades as a very accurate technique for measuring bonding-sensitive structure factors.^[175,195–208] It involves calculating CBED patterns and fitting them iteratively to experimental ones by adjusting the parameters to which the patterns are sensitive (these include the bonding-sensitive structure factors). The precision AND accuracy come from the fact that a full dynamical scattering calculation of intensity as a function of scattering angle is being fitted to an experimental intensity distribution, i.e., a CBED pattern, as opposed to the integrated intensities of reflections in point diffraction patterns, as is the case in X-ray diffraction. QCBED results in massive overdetermination of the refined structure factors as of order 10 parameters are outnumbered by $\sim 10^4$ data points in the matched intensity distribution of a CBED pattern. QCBED is more computationally intensive than X-ray diffraction analysis; however, with fast computers and highly linear electron-sensitive area detectors on modern electron microscopes, QCBED is emerging as the technique of choice when it comes to requiring very high precision and accuracy in bonding-sensitive structure factor measurements.

In aluminum, the need for precision and accuracy is possibly even more crucial than in bonding electron density studies of other materials. This is because aluminum's maximum bonding electron density is tiny ($\sim 0.047 \text{ e}^{-}\text{\AA}^{-3}$ based on the structure factors of Nakashima et al.^[175]) compared with the experimental benchmark in X-ray diffraction of diamond, for example, where the maximum bonding density is more than an order of magnitude greater ($\sim 0.66 \text{ e}^{-}\text{\AA}^{-3}$ using the structure factors of Ref. [209]). In other words, to measure bonding in aluminum, the experiments have to be at least an order of magnitude more sensitive than in a material like diamond. This is where QCBED comes into its own as an experimental technique.

It is QCBED that gave rise to the experimental measurements presented in Ref. [175], which can be considered the modern benchmark for bonding in aluminum, due to the precision and accuracy obtained from the technique.

The same requirements of precision and accuracy can be imposed on theoretical, *ab initio*, modeling and calculation of the bonding electron density in aluminum. Since the advent of density functional theory (DFT),^[210] a significant number of publications on the theoretical calculation of the bonding electron distribution in aluminum have appeared using different approximations within the framework of DFT.^[175–186] The results are varied and depend on the approximations made. The two historical approaches that are closest to the experimental benchmark set by QCBED in Ref. [175] are the augmented plane wave (APW) calculations of Perrot^[180] and the “atom in jellium” model of Rantala.^[186] The former made fewer approximations by extending beyond the non-muffin tin constraints prevalent in contemporary calculations. It is in fact very similar in nature to the DFT calculation presented in Ref. [175], which used the full potential linearly APW (FP-LAPW) approach and the generalized gradient approximation (GGA) with local orbital (lo) and local screening (ls) pseudopotentials. The proximity of the benchmark QCBED measurements in Ref. [175] to the atom in jellium model of Rantala^[186] is in itself a testament to aluminum being an excellent approximation to the Drude model of ideal metals being a lattice of cations in a sea of delocalized electrons.

The importance of precision and accuracy in bonding studies is highlighted by the following review of all bonding electron density studies, both experimental and theoretical, published to date for aluminum. In order to present all of these historical results in a coherent fashion, key locations within the crystal structure of aluminum are considered. Figure 10 presents the fcc unit cell of aluminum and revisits the tetrahedral and octahedral interstices discussed in the “The Crystal Structure of Pure Aluminum” section. These are marked in the figure together with the bridge center, which is defined as the midpoint between nearest neighbor atoms. Each of the positions is marked with a cross in the unit cell, and the dotted lines represent the coordination of each of these positions with their nearest atoms. The bonding electron density at each of these positions can be calculated for any set of published structure factors, thus allowing each published study to be graphed as a point in a three-dimensional plot with axes corresponding to the bonding electron densities at the tetrahedral, octahedral, and bridge centers.

Here, as in Ref. [175], the bonding electron density is calculated for each of the published sets of structure factors by subtracting the independent atom model (IAM) structure factors based on Doyle’s and Turner’s landmark relativistic Hartree–Fock calculations of electron density for noninteracting, isolated neutral atoms (unbonded).^[211] This proceeds according to the following equations, which follow on from Eq. 7:

Fig. 10 A diagram of the fcc unit cell of aluminum showing the key bonding locations and their coordination to nearest neighbor atoms. The tetrahedral and octahedral interstitial positions (marked “tet.” and “oct.” respectively) were previously identified in Fig. 1C. A third position of importance in bonding studies is the bridge center (as marked) which is at the midpoint between nearest neighbor atoms. As shown by the dotted lines, the bridge center has a coordination number of two atoms, whereas the tetrahedral and octahedral centers have coordination numbers of four and six atoms respectively. It is interesting to note that of the three positions, only the tetrahedral center does not lie on a line between any of its coordinated atoms. The tetrahedral, octahedral, and bridge centers have coordinates of 0.25 0.25 0.25, 0.5 0.5 0.5, and 0.25 0.25 0.00, respectively. This figure was drawn with the aid of VESTA^[1]

$$\Delta\rho(\mathbf{r}) = \rho(\mathbf{r})^{\text{actual}} - \rho(\mathbf{r})^{\text{IAM}}$$

$$= \frac{\sum_{\mathbf{g}} F_{\mathbf{g}}^{\text{actual}} e^{-2\pi i \mathbf{g} \cdot \mathbf{r}}}{V_{\text{cell}}} - \frac{\sum_{\mathbf{g}} F_{\mathbf{g}}^{\text{IAM}} e^{-2\pi i \mathbf{g} \cdot \mathbf{r}}}{V_{\text{cell}}}, \quad (10)$$

$$\therefore \Delta\rho(\mathbf{r}) = \frac{\sum_{\mathbf{g}} (F_{\mathbf{g}}^{\text{actual}} - F_{\mathbf{g}}^{\text{IAM}}) e^{-2\pi i \mathbf{g} \cdot \mathbf{r}}}{V_{\text{cell}}}. \quad (11)$$

Here, $\Delta\rho(\mathbf{r})$ is generally referred to as the deformation electron density. It is a measure of the deviation of the measured or calculated total electron density, $\rho(\mathbf{r})^{\text{actual}}$, from the total electron density given by the IAM, $\rho(\mathbf{r})^{\text{IAM}}$. As Eq. 11 shows, $\Delta\rho(\mathbf{r})$ is simply the Fourier sum of the differences between the structure factors measured in an experiment or calculated by a theory that models a bonded crystal, $F_{\mathbf{g}}^{\text{actual}}$, and those calculated for a procystal of unbonded atoms, $F_{\mathbf{g}}^{\text{IAM}}$. Division is always by the cell volume, V_{cell} , which results in $\Delta\rho(\mathbf{r})$ having units of $\text{e}^{-\text{\AA}^{-3}}$. Note that if $\Delta\rho(\mathbf{r})$ is positive, then this is known as the bonding electron density, whereas if it is negative, it is known as the antibonding electron density.

Equation 11 and the IAM structure factors for aluminum from Doyle and Turner^[211] have been applied to all published sets of structure factors^[126,127,129,130,133,140,144,149,152,154,167–186] for aluminum, which nominally constitute $F_{\mathbf{g}}^{\text{actual}}$ and details of which are given in Appendix D. The definitions, $\Delta\rho_{\text{tet}} = \Delta\rho(0.25, 0.25, 0.25)$ (the tetrahedral center in Fig. 10), $\Delta\rho_{\text{oct}} = \Delta\rho(0.5, 0.5, 0.5)$ (the octahedral center in Fig. 10), and $\Delta\rho_{\text{bridge}} = \Delta\rho(0.25, 0.25, 0)$ (the bridge center in Fig. 10), establish the three axes in Fig. 11.

Fig. 11 Plots of all experimental^[126,127,129,130,133,140,144,149,152,154,167–175] and theoretical^[175–186] determinations of deformation electron density, $\Delta\rho$, in aluminum to date. Note that the deformation electron density is computed by subtracting the IAM structure factors according to Doyle and Turner^[211] from each set of published structure factors. This allows the computation of the Fourier sum that gives the deformation of the electron density from neutral, unbonded atoms. The three-dimensional plot (labeled only in their two-dimensional projections in order to reduce clutter) are the deformation electron densities at the tetrahedral ($\Delta\rho_{\text{tet}}$), octahedral ($\Delta\rho_{\text{oct}}$), and bridge ($\Delta\rho_{\text{bridge}}$) centers in the x , y , and z axes of the plot, respectively. The red points show the distribution of all experimentally determined $\Delta\rho_{\text{tet}}$, $\Delta\rho_{\text{oct}}$, and $\Delta\rho_{\text{bridge}}$ prior to the most recent experiments of Nakashima et al. using QCBED^[175] (green point). The blue points in the plot comprise all of the theoretical determinations prior to the latest calculations of Nakashima et al.^[175] in which the FP-LAPW approach and GGA (+lo +ls) were applied using the WIEN2K package^[212] (purple point). To give a better impression of the spread of all of the determinations, the three-dimensional plot is projected along each of its axes to form the two-dimensional plots shown. Error bars are intentionally omitted from the experimental points in the three-dimensional plot in order to minimize the obscuration of points by error bars from nearby points. It is noteworthy that the errors associated with the latest QCBED measurements of bonding in aluminum are much smaller than previous experiments. The points marked “P,” “R,” and “I” refer to the separate theoretical calculations of Perrot^[180] and Rantala^[186] and the experimental measurements of Inkinen et al.,^[144] respectively. These are the only points from structure factor determinations prior to the work of Nakashima et al.,^[175] which fall within the bounds of error associated with the benchmark QCBED measurement (green point) presented in Ref. [175]

Figure 11 shows a three-dimensional plot of $\Delta\rho_{\text{tet}}$, $\Delta\rho_{\text{oct}}$, and $\Delta\rho_{\text{bridge}}$ with each published set of structure factors determined experimentally, prior to Nakashima et al.,^[175] constituting a red cube; each published set of theoretically calculated structure factors, prior to Nakashima et al.,^[175] constituting a blue sphere; and the most recent experimental and theoretical work of Nakashima et al.^[175] constituting the green cube and purple sphere, respectively. The three-dimensional plot of all of these points occupies the center of the figure, and the left, right, and bottom sides show projections of this plot onto separate two-dimensional plots perpendicular to the $\Delta\rho_{\text{tet}}$, $\Delta\rho_{\text{oct}}$, and $\Delta\rho_{\text{bridge}}$ axes, respectively. The error bars, shown only in the two-dimensional plots in order to reduce crowding in the three-dimensional plot, are very large for all experimental determinations prior to the work of Nakashima et al.^[175]

The QCBED determination of Nakashima et al.^[175] has much smaller error bars than previous experiments and defines a much narrower range of uncertainty in the distribution of the deformation electron density. The green point, which represents these latest measurements by QCBED, is very close to and encloses within its margins of error the DFT calculation presented in Ref. [175] and shown here as the purple point. The calculation used the FP-LAPW approach and the GGA with local orbital (lo) and local screening (ls) pseudopotentials.

The DFT calculation of Nakashima et al.^[175] (green point in the plots of Fig. 11) is not far from the atom in jellium model of Rantala^[186] and the APW calculation of Perrot^[180] discussed previously. Agreement with the model of Perrot^[180] (marked by the black “P” in Fig. 11) is understandable because both calculations are very similar in nature as previously explained. Agreement with the QCBED experiment^[175] and the atom in jellium model of Rantala^[186] (marked by the black “R” in Fig. 11) suggests that the theoretical treatment of aluminum as very closely approximating an ideal Drude metal is remarkably close to the truth as well as being well modeled by the theoretical approach taken in Ref. [175]. The points in the graph resulting from Perrot’s^[180] and Rantala’s^[186] calculations

are also within the range of uncertainty of the QCBED measurements.

The only experimental point that lies within the range of uncertainty of the QCBED measurements of Nakashima et al.^[175] comes from the X-ray diffraction study of Inkinen et al.^[144] (marked with a black “I” in Fig. 11). They used powder samples that were pressed into slabs with pressures just below 50 MPa. These pressures were found low enough to cause no orientational texture within the pressed samples, yet they were sufficiently high to eliminate significant effects in the integrated diffracted intensities caused by surface roughness or specimen porosity. The advantage of powders with small grain sizes in X-ray diffraction is that extinction effects caused by multiple scattering are minimized by a short path length through any given grain. This is the likely reason for the agreement between this X-ray study^[144] and the QCBED study of Nakashima et al.,^[175] within the error associated with the latter study.

Evident from Fig. 11 is the large spread in the experimental and theoretical determinations of the deformation electron density in aluminum. This is what necessitated a more accurate and precise study, furnished by QCBED,^[175] to resolve the ambiguities of all the preceding bonding studies in this nearly free electron gas. The mean and uncertainty of all experimental and theoretical structure factor determinations in aluminum prior to the work of Nakashima et al.^[175] are now considered and compared with the QCBED measurements and the DFT calculation presented in Ref. [175] (Table 3).

Table 3 summarizes the four lowest order (i.e., lowest scattering angle) structure factors of aluminum for all experiments prior to Nakashima et al.,^[175] all theoretical calculations prior to Nakashima et al.,^[175] the QCBED measurement of Nakashima et al.,^[175] and the DFT calculation of Nakashima et al.^[175] The table gives the mean value of each structure factor and the associated uncertainty, which is determined from the spread in the determinations plus the error bars associated with each determination in the case of the experimental studies. The DFT calculation of Nakashima et al.^[175] used the well-known WIEN2K

Table 3 Summary of the four lowest order (lowest $(\sin\theta)/\lambda$) structure factors of aluminum as determined by all experimental and theoretical work prior to and including Ref. [175]

hkl	F_{hkl} (e-/atom) experiments prior to Nakashima et al. ^[175]	F_{hkl} (e-/atom) theory prior to Nakashima et al. ^[175]	F_{hkl} (e-/atom) QCBED ^[175]	F_{hkl} (e-/atom) WIEN2K GGA/ FP-LAPW +lo +ls ^[175,212]	F_{hkl} (e-/atom) IAM ^[211]
1 1 1	8.8 ± 0.2	8.86 ± 0.07	8.87 ± 0.01	8.87	8.95
0 0 2	8.4 ± 0.2	8.40 ± 0.08	8.37 ± 0.01	8.38	8.50
0 2 2	7.3 ± 0.1	7.31 ± 0.07	7.31 ± 0.03	7.30	7.31
1 1 3	6.6 ± 0.1	6.65 ± 0.05	6.64 ± 0.06	6.64	6.65

Note: The values and uncertainties reflect the mean values of all published structure factors and their standard deviation from their respective means. A comparison is made between all work prior to Nakashima et al.,^[175] the results from Ref. [175] and the IAM according to the relativistic Hartree–Fock calculations of Doyle and Turner,^[211] which, at present, are taken as the standard reference for electron distribution around neutral, independent (unbonded and noninteracting) atoms. The results in Ref. [175] are taken as the most accurate determinations of bonding in aluminum to date.

software package developed by Blaha et al.^[212] The final column of the table presents the IAM calculated structure factors. Differences between structure factors listed in the other columns and those of the IAM are associated with the deformation of the electron density from that of spherical noninteracting neutral atoms to the bonded real structure determined from the averages of the different approaches. It can immediately be seen in Table 3 that the uncertainties associated with the experimental structure factors (column 2) are much larger than the differences between these structure factors and those of the IAM (column 6). It can therefore be concluded that the averages of the experimental structure factors measured prior to Nakashima et al.^[175] are unable to determine bonding in aluminum with any certainty whatsoever.

Considering the averages of the structure factors from all theoretical determinations prior to Nakashima et al.,^[175] the uncertainties due to the spread of these determinations are somewhat smaller than the experimental uncertainties in column 2 of Table 3. The uncertainties are in fact smaller than the differences between the averages of the theoretically calculated structure factors and the corresponding IAM values. However, the spread in these determinations is still large enough to leave significant doubt as to where the truth lies.

The QCBED measurements of Nakashima et al.^[175] have uncertainties associated with each structure factor that are an order of magnitude smaller than the preceding results in the table. This increases the confidence in these results being able to say something definitive about the distribution of bonding electron density within aluminum. Furthermore, the agreement with the most recent DFT calculation, using the most up-to-date formalisms, approximations, and software (WIEN2K^[212]), presented in Ref. [175], is well within the margins of error of the QCBED measurements.

In Figs. 12–15, the average structure factors and their uncertainties in each of the columns in Table 3 are explored in greater detail with respect to the bonding electron distribution determined from these sets of structure factors. Figure 12, the first of these figures, plots the deformation electron density determined from each set of structure factors in Table 3 by first subtracting the IAM values from them and applying Eq. 11. These determinations constitute the solid points plotted in the three-dimensional plot whose axes are the same as those in Fig. 11, namely, $\Delta\rho_{\text{tet}}$, $\Delta\rho_{\text{oct}}$, and $\Delta\rho_{\text{bridge}}$. In addition to these central points, the uncertainties associated with the corresponding mean structure factors in Table 3 are used to calculate the range of possible $\Delta\rho_{\text{tet}}$, $\Delta\rho_{\text{oct}}$, and $\Delta\rho_{\text{bridge}}$ values associated with each set of structure factors. These ranges are shaded: red for all experimental determinations prior to the work of Nakashima et al.,^[175] blue for all theoretical calculations prior to the work of Nakashima et al.,^[175] and green for the QCBED measurements of Nakashima et al.^[175] and their associated uncertainties. The focus in Fig. 12 is on the experiments prior to Nakashima et al.,^[175] and the spread (red region)

is significantly larger than the spread associated with the historical theoretical determinations (blue region) and much larger than the spread in the QCBED determination of $\Delta\rho(\mathbf{r})$ (green region).

Specific plots of the bonding electron density (positive $\Delta\rho(\mathbf{r})$) in the fcc cell of aluminum are presented in Fig. 12 for specific positions in the range of $\Delta\rho_{\text{tet}}$, $\Delta\rho_{\text{oct}}$, and $\Delta\rho_{\text{bridge}}$ spanned by the historical experimental measurements prior to Nakashima et al.^[175] Position A is at the point of minimum $\Delta\rho_{\text{tet}}$ in the region, whereas position B is at the point of maximum $\Delta\rho_{\text{bridge}}$ in the region. Position C is at the point of minimum $\Delta\rho_{\text{oct}}$, D is at the point of minimum $\Delta\rho_{\text{bridge}}$ and maximum $\Delta\rho_{\text{oct}}$, and E is at the point of maximum $\Delta\rho_{\text{tet}}$. The bonding electron density plot labeled F is from the point at the center of the region of uncertainty, marked by the red cube, and corresponds to the mean structure factors in column 2 of Table 3.

All bonding electron density iso-surface plots in the present review are drawn with an iso-surface level at 50% of the maximum $\Delta\rho(\mathbf{r})$ in a cell for the set of structure factors being used.

In the present case, considering the historical experimental determinations of $\Delta\rho(\mathbf{r})$ (prior to Nakashima et al.^[175]), the variation in types of bonding presented in each cell from each position in the region of uncertainty is large. In cell A, the iso-surface at 50% of the maximum $\Delta\rho(\mathbf{r})$ in the cell encloses bonding volumes centered within the octahedral interstices with holes at the centers. Cell B shows strong transverse bridge bonding (i.e., where the bridge bonds are elongated perpendicularly to the line between the bridged atoms) and holes at the tetrahedral centers. Cell C shows very strong linear bridge bonding (i.e., the bridge bonds are elongated along the line between the bridged atoms) and cell D shows highly concentrated octahedrally-centered bonding. Cell E shows strongly concentrated tetrahedrally-centered bonds, and F shows a hole at the octahedral centers with elevated bonding density at the tetrahedral centers and in transverse bridge bonds.

Figure 13 shows the experimental spread stripped away to reveal the spread in theoretical determinations prior to Nakashima et al.^[175] more vividly. The form of the figure is the same as Fig. 12. The blue-shaded region is more constricted in comparison with the red region which embodied the historical experimental measurements prior to Nakashima et al.^[175] This is to be expected as the uncertainties in Table 3 are much smaller for the theoretical determinations than for the historical experimental determinations. Cells A–F show the bonding electron density iso-surface (at 50% of the maximum $\Delta\rho(\mathbf{r})$ in each cell) for the same points in the blue region of uncertainty as points A–F in Fig. 12 for the red region. Cell A shows a bonding network with holes at the tetrahedral and octahedral centers, with the main concentration occurring in the bridges. Cell B shows strong transverse bridge bonding with holes at the octahedral centers, whereas C shows more linear bridge bonding

Fig. 12 Plots of the spread in deformation electron density predicted by the mean and margin of error of all the structure factors in Table 3. The red-shaded region in the three-dimensional plot shows the extent of all possible outcomes from the mean structure factors and their uncertainties determined from all experimental studies prior to that of Nakashima et al.,^[175] listed in column 2 of Table 3. The actual distributions of the bonding electron density at various points in the region are shown for single unit cells with arrows pointing to the corresponding region of the plot. The locations have the following significance in bounding the region: (A) the point of minimum $\Delta\rho_{\text{tet}}$; (B) the point of maximum $\Delta\rho_{\text{bridge}}$; (C) the point of minimum $\Delta\rho_{\text{oct}}$; (D) the point of minimum $\Delta\rho_{\text{bridge}}$, which is also the point of maximum $\Delta\rho_{\text{oct}}$; (E) the point of maximum $\Delta\rho_{\text{tet}}$; and (F) the point at the center of the region. The iso-surface plots are at a level of 50% of the maximum bonding density in each cell. Also shown in the graph are the regions of deformation electron density spanned by the mean structure factors and their uncertainties determined from all theoretical calculations preceding Ref. [175] (column 3 of Table 3; shaded in blue) and from the QCBED measurements of Nakashima et al.^[175] (column 4 of Table 3; shaded in green). The points corresponding to the mean deformation density distribution for each of these sets of structure factors are shown with red, blue, and green points, respectively. In this figure, the relevant point, for which the mean bonding density is shown in the dotted cell (F), is the red cube at the center of the red-shaded region. An additional point, a purple sphere, shows the location in the plot of the WIEN2K^[212] calculated results from Ref. [175] (column 5 of Table 3). All deformation densities plotted were determined by subtraction of the IAM^[211] structure factors (listed in column 6 of Table 3) from each of the other sets of structure factors listed in Table 3. The cells in this figure were plotted with VESTA^[1]

and very significant holes at the octahedral centers. Cell D, as in the case of the experimental spread, shows strong octahedrally-centered bonds, and E shows small octahedrally-centered bonding density concentrations and much stronger concentrations at the tetrahedral centers. Cell F, showing the average of all of the theoretical determinations prior to Nakashima et al.,^[175] is indicative of tetrahedrally-centered bonding.

So far, in view of the different bonding distributions possible within the spread of experimental and theoretical studies prior to Nakashima et al.,^[175] a definitive conclusion is difficult to draw. This is where an experimental technique with very high precision and accuracy, such as QCBED, can make a definitive assessment.

Figure 14 strips away the blue shaded region of theoretical uncertainty examined in Fig. 13, to reveal the highly

constricted green region, which represents the uncertainty associated with the QCBED measurements of Nakashima et al.^[175] Again, cells A–F correspond to the same significant points in the green (QCBED) region of uncertainty as in previous graphs for the red (previous experiments) and blue (previous theoretical determinations) uncertainties. In all cases, the bonding is dominantly tetrahedrally-centered, with no indication of any octahedrally-centered bonding at all. Cells A–C show some significant concentrations of bonding electron density at the bridge centers, and in every case, the form of the bonding is transverse in the bridges. Cells D–F all show nearly identical bonding concentrations, which are exclusively tetrahedrally-centered. It is important to note that morphologically, tetrahedrally-centered bonds that have a larger spatial extent will lead to significant bonding electron density at the bridge centers.

Fig. 13 As per Fig. 12, except that the red region and corresponding bonding density plots are hidden, with the focus here being on all the theoretical calculations preceding Ref. [175] (column 3 of Table 3; shaded in blue). Again, the letter of each cell corresponds to the same point for the blue region as described for the red region in Fig. 12, and the dotted cell (F) indicates the mean bonding electron density determined from all theoretical calculations preceding Ref. [175], which is the center of the blue region indicated by the blue sphere. All iso-surfaces are drawn at a level of 50% of the maximum bonding density in a cell for each region. The cells in this figure were plotted with VESTA^[1]

Fig. 14 As per Fig. 12, except here the focus is on the most recent experimental measurement of bonding in the literature,^[175] colored in green and corresponding to column 4 in Table 3. Again, each cell corresponds to the same point for the green region, examined here, as described for the red and blue regions of the preceding figures (Figs. 12 and 13). The dotted cell (F) indicates the mean bonding electron density determined by the QCBED study of Nakashima et al.,^[175] which is at the center of the green region indicated by the green cube. All iso-surfaces are drawn at a level of 50% of the maximum bonding density in each cell. The cells in this figure were plotted with VESTA^[1]

Furthermore, what is evident from the consistency of the iso-surfaces near the bridge centers in cells A–C is that the shapes of the associated tetrahedrally-centered bonds are all the same in cells A–C. Close inspection of the iso-surfaces in cells D–F reveals that if the surfaces were expanded about the tetrahedral centers, the intersection with the cell faces at the bridge positions would result in transverse forms similar to those observed in cells A–C.

The very high precision of the QCBED measurements of Nakashima et al.^[175] affords the first definitive experimental conclusion that bonding in aluminum is almost purely tetrahedral in nature. As discussed in Ref. [175], even relatively recent theoretical studies by Kioussis et al.^[213] and Ogata et al.,^[214] published almost simultaneously but without structure factors, are at odds about the bonding in aluminum. The former study^[213] was correct in asserting that the bonds are tetrahedrally-centered, whereas the latter study^[214] asserted that they are octahedrally-centered. This means that the mechanical properties of aluminum derived in Ref. [214] from that assessment of bonding were based on an incorrect bonding electron distribution.

Finally, it remains to make one final comparison based on the summary of structure factors in Table 3. This is shown in Fig. 15, where the mean values in columns 2–5

of the table are plotted in terms of $\Delta\rho_{\text{tet}}$, $\Delta\rho_{\text{oct}}$, and $\Delta\rho_{\text{bridge}}$. It is worth noting in this comparison that all of the points (representative of the centers of the spreads illustrated in Figs. 12–14) in the graph are very close together. It is therefore not surprising that they yield very similar plots of the bonding electron density iso-surface. In all cases, the morphologies indicate tetrahedrally-centered bonding. All cases with the exception of cell A show iso-surfaces (at 50% of the maximum bonding density) that fully enclose only the tetrahedral center. In the case of cell A, which represents the mean of all experimental studies prior to Nakashima et al.,^[175] the iso-surface encloses a much greater expanse, centered on the tetrahedral interstices and including the bridge centers. The iso-surface intersects the cell walls in a manner very similar to the extremes of the QCBED measurements shown in cells A–C in Fig. 14, namely, in a form that is transverse to the bridge between the nearest neighbor atoms. Cell D in Fig. 15 shows the WIEN2K^[212] DFT calculation of the bonding electron density, carried out in Ref. [175] using the FP-LAPW method and the GGA with local orbital (lo) and local screening (ls) pseudopotentials. It is in very close agreement with the QCBED result as well as the average of all previous theoretical studies.

Fig. 15 Comparison of the bonding electron densities determined from the structure factors in each column of Table 3. (A) The mean of all experimental measurements prior to the QCBED study of Nakashima et al.^[175] constitutes the red cube in the deformation density graph and the red iso-surface plot of bonding electron density in the red dotted cell (as in Fig. 12F). (B) The mean of all theoretical determinations prior to the WIEN2K calculation of Nakashima et al.^[175] constitutes the blue sphere in the deformation density graph and the blue iso-surface plot of bonding electron density in the blue dotted cell (as in Fig. 13F). (C) The mean bonding electron density determined by the QCBED study of Nakashima et al.^[175] is given here by the green cube in the graph and the green iso-surface plot of bonding electron density in the green dotted cell (as in Fig. 14F). (D) The purple sphere and purple iso-surface plot of bonding electron density correspond to the WIEN2K^[212] calculation performed in Ref. [175] (column 5 in Table 3). All iso-surfaces are drawn at a level of 50% of the maximum bonding density in each cell. The cells in this figure were plotted with VESTA^[1]

A final observation, based on Fig. 15, is that in the absence of the QCBED result of Nakashima et al.,^[175] the graph would contain two closely related, theoretically derived points, giving rise to almost equivalent bonding electron density distributions as plotted in cells B and D. With experimental measurements being the only true window into what exists in nature, the morphological differences between A and B and D would only serve to question the accuracy and validity of the latest solid-state theory (DFT), even in such a very simple system as aluminum. By providing an accurate and highly precise experimental benchmark, the QCBED results of Nakashima et al.^[175] serve to validate some forms of DFT over others, with some approximations being shown to be better than others. Using the average of past experiments as a benchmark for validating different approaches to DFT may have led to the wrong conclusions, even in such a simple material. This would not bode well for theoretical studies of more complex systems such as aluminum alloys, for example.

THE CRYSTALLOGRAPHY OF (SOME) ALUMINUM ALLOYS

In the first four sections, the following fundamental aspects of the crystallography of pure aluminum were discussed at length: (i) the crystal structure, (ii) the lattice parameter, (iii) the thermal vibration amplitude (DWF) of elemental aluminum, and (iv) the bonding electron distribution in aluminum. In this section, all of these aspects are brought to bear on the crystallography of aluminum alloys in the form of a general discussion, using a number of well-known examples, and a review of key literature on the crystallography of some significant aluminum alloys.

For the sake of brevity, it is impossible to discuss the crystallography of all aluminum alloys in this section. It is also impossible to detail and review all of the techniques used to characterize aluminum alloys and their constituent phases. This section therefore provides a perspective for considering the crystallography of aluminum alloys and illustrates the ideas presented with a small number of examples which have gained significant attention in the scientific literature.

Before commencing, however, it is worth giving a very brief review of the vast literature discussing the characterization and application of aluminum alloy crystallography. In the following text, a very simple and brief summary is given in order to provide a few illustrative examples of pioneering, developmental, and state-of-the-art research into the atomic structure of aluminum alloys.

Aluminum alloys fall into the following classes or series (references are a selection of works involving crystallographic characterization of alloys that fall within each class and that may not otherwise have been cited in other parts of the present review). Note that where a

code has not been designated to the alloy being studied, the alloy has been assigned a class based on the main alloying element):

- 1xxx—Commercially pure aluminum (having a minimum purity of 99%).^[215–219]
- 2xxx—Copper (Cu) is the main alloying element.^[219–283]
- 3xxx—Manganese (Mn) is the main alloying element.^[284–292]
- 4xxx—Silicon (Si) is the main alloying element.^[219,293–303]
- 5xxx—Magnesium (Mg) is the main alloying element.^[275,304–312]
- 6xxx—Magnesium (Mg) and silicon (Si) are the main alloying elements.^[230,234,242,243,267,278,287,313–359]
- 7xxx—Zinc (Zn) is the main alloying element.^[230,234,267,278,287,360–379]
- 8xxx—Other elements including rare earths are used as the main alloying elements.^[216,245,286,287,380–408]
- High-entropy alloys (HEAs).^[409]

An extensive generic review in terms of structure and properties is given by Mondolfo,^[410] giving almost complete coverage of all aluminum alloys with the exception of those that have been developed since the 1980s.

The characterization, analysis, prediction, and modeling of aluminum alloy crystallography, structure, and composition have involved the following techniques (references from the list above are associated with each of the techniques involved in each of the works).

Experimental Methods

- X-ray diffraction^[218,220–225,237,264,270,277,285,286,289,293,294,376,386,387,394,397,402–404,409]

These lists are only small subsets of all of the existing literature on the experimental and theoretical investigation of the crystallography, composition, and structure of aluminum alloys. They are biased toward more recent work but also include some examples of landmark pioneering research. They do not cover all systems that have been explored or that are being explored. It is emphasized again that the references given here serve to provide just a taste for the vast research into the crystallography of aluminum alloys.

At this point, it is worth returning to the key concepts developed and explored for pure aluminum, in order to apply them to aluminum alloys.

Crystal Structures of (Some) Aluminum Alloys

Alloys can take the form of a solid solution, which has a homogeneous crystal structure of the same form (single phase) everywhere (allowing for changes in orientation from grain to grain in a polycrystalline microstructure and also allowing for crystal defects within each grain). Alternatively, alloys can consist of a dominant matrix phase, or a parent crystal structure, containing a dispersion of intermetallic precipitates that have different crystal structures and compositions to the matrix and make up a small volume fraction of the alloy. Eutectic mixtures consist of interleaved metallic phases of differing compositions which dominate the microstructure.^[412]

The majority of commercial and research interest in aluminum alloys is in age-hardenable alloys (or precipitation hardening alloys), which begin as supersaturated solid solutions (SSSSs). These are subjected to aging heat treatments, which result in the migration of solute atoms to points of nucleation of intermetallic phases. Often, a crystallographic phase transformation ensues in the formation of a critical nucleus for a precipitating intermetallic phase, which grows until the local concentration of solute atoms decreases below a critical concentration or crystallographic barriers to precipitate growth stop the process.

In cases where the intermetallic precipitates act as strong barriers to the movement of dislocations, strengthening occurs. Where they promote or mediate the movement of dislocations, the alloy is embrittled or weakened. In a rather hand-waving manner of describing precipitation-hardened alloys, the metaphor is that the precipitates act as a strengthening scaffold in an otherwise relatively weak matrix.

Pure aluminum (99.999+% purity) has an ultimate tensile strength (UTS) of 40–50 MPa,^[410] whereas some of the strongest precipitation-hardened alloys have UTSs exceeding 700 MPa (e.g., Weldalite 049 which is an Al–Cu–Li–Mg–Ag–Zr alloy).^[413] This massive increase in strength means that these types of alloys have a very high strength-to-weight ratio that makes them competitive with high-strength steels. The alloying elements are present at concentrations of only a few atomic percent, and therefore, changes in density compared to pure aluminum are negligible in the face of the 10- to 20-fold gains in strength. These gains in strength are largely due to the scaffolding effect of high-aspect-ratio strengthening precipitates that inhibit dislocation movement within the alloys.

This section presents examples of the most prominent strengthening precipitate phases that have been the focus of significant research. These include the θ'' (Al_3Cu), θ' (Al_2Cu), and θ (Al_2Cu) precipitate phases in Al–Cu-based alloys,^[104,220,230,239,245,261–263,268,271] the T_1 phase (Al_2CuLi) in

Al–Cu–Li-based alloys,^[225,241,245,259,260,268,272,279–281] the Ω phase (Al_2Cu) in Al–Cu–Mg–Ag alloys,^[226,230,231,235,239,245,274] and the S phase (Al_2CuMg) in Al–Cu–Mg alloys.^[229,230,234,239,245,251,252,256,258] All of these alloy systems fall within the 2xxx and 8xxx series of aluminum alloys, but the crystallographic concepts explored here are equally applicable in the other series and, consequently, to other intermetallic precipitate phases and solid solutions.

Figure 16 illustrates a binary Al–Cu alloy with copper atoms present at an atomic concentration of $\sim 4\%$. Given that the maximum solid solubility of copper in aluminum is 2.4 atomic percent,^[413] Fig. 16A represents a SSSS.

Copper atoms are too large to fit into any interstitial sites within the fcc lattice of aluminum, and they are thus substitutional. Note that distortions of the lattice due to the smaller copper atoms are not drawn into this depiction of the Al–Cu solid solution. Heat treatment (artificial aging)

of this SSSS results in the possible formation of numerous phases including Guinier–Preston (GP) zones^[414,415] (which are single continuous planes of copper atoms substituted on aluminum lattice sites), θ'' precipitates (consisting of multiple GP zones separated by three $\{002\}$ planes of aluminum (see Table 4)), θ' precipitates (shown in Fig. 16B and Table 4), and eventually, the stable θ phase (see Table 4).

GP zones, θ'' , and θ' are all metastable phases, whereas the θ phase is the end product of the solid-state reaction: $\text{SSSS} \rightarrow \text{GP} + \theta'' + \text{matrix} \rightarrow \theta' + \text{matrix} \rightarrow \theta + \text{matrix}$. It is the θ' phase that is the most effective strengthening precipitate, and processing routes for Al–Cu-based alloys are frequently tailored to promote a high number density of θ' precipitates. Figure 16B shows a block of Al–Cu alloy containing a θ' precipitate that is sandwiched on both major $\{001\}$ facets by the aluminum matrix. Figure 16C

Fig. 16 An illustration of the θ' phase (Al_2Cu) embedded in the aluminum alloy matrix. The precursor SSSS is illustrated with a $10 \times 10 \times 10$ fcc unit cell block containing randomly placed copper atoms at a concentration of approximately 4 at.% (A). Aluminum alloy solid solutions are usually always substitutional, as shown in the present case. After heat treatment, precipitates can form, such as the segment of θ' phase (B). The unit cell of θ' is shown in part C, and the fcc unit cell of aluminum is shown for comparison beneath it (D). (E) A slice one unit cell thick is taken through the precipitate structure and the surrounding matrix to show the relationship between the precipitate and matrix structures. A situation of minimal volumetric strain is illustrated which involves a precipitate thickness of 3.5 unit cells of θ' in the c -axis of θ' , which corresponds to nearly 5 fcc unit cells of aluminum. This θ' thickness of $3.5c_{\theta'}$ is known as a “magic thickness”.^[262] This figure illustrates a binary alloy (two elements) and was drawn with the aid of VESTA^[1]

Table 4 A summary of selected common precipitate phases occurring in aluminum alloys, their unit cell structures, orientation relationships, and misfit with the aluminum matrix

Notes: The different unit cells that can be used to describe the structure of the aluminum matrix, explored in Fig. 3, are used here to simplify the description of orientation relationships and lattice mismatch. All unit cells and axes were drawn with VESTA,^[1] using structural information compiled from Refs. [66,220,226,229,234,245,252,259–262,280,413,423–437].

and D show the unit cells of θ' and the aluminum matrix in the orientation relationship they have within the alloy. The tetragonal cell of θ' has very similar a and b lattice parameters to the corresponding lattice parameters in the Al_{fcc} cell shown in Fig. 16D, with only a 0.2% linear misfit (see also Table 4). The c lattice parameter of θ' , $c_{\theta'}$, is significantly different and can impart a large amount of strain in the direction normal to the θ' precipitate. This strain is minimized for certain multiples of $c_{\theta'}$, which span thicknesses that are very close to integer multiples of the aluminum matrix c lattice parameter, $c_{\text{Al,fcc}}$. One such case is drawn in both Fig. 16B and E where $3.5c_{\theta'}$ is approximately equal to $5c_{\text{Al,fcc}}$ (i.e., to within 0.3%). This is known as a “magic thickness”.^[262] Other magic thicknesses for θ' precipitates are given in Table 4 where the magic thicknesses of $2c_{\theta'}$ and $3.5c_{\theta'}$ are highlighted in red because these are the most commonly observed thicknesses of θ' in Al–Cu alloys.^[262] Figure 16E shows a section through the modeled θ' precipitate and the surrounding matrix with all atoms drawn in a non-space-filling manner and with a depth of only one unit cell so that the orientation relationship between the θ' unit cell and the Al matrix fcc unit cell can be clearly seen.

Although the θ' unit cell has no face-centered copper atoms in the basal plane of the cell, the interfaces of the main facets of θ' precipitates with the aluminum matrix are observed experimentally to have extra face-centered copper atoms.^[261] DFT calculations show that this configuration has a lower energy than one in which the θ' precipitates terminate without the extra face-centered copper atoms.^[261] This is an excellent example of where new capabilities in electron microscopy, due to aberration correction, have allowed such crystallographic detail to be resolved.

The crystallographic relationships (orientation relationships) between GP zones, θ'' , θ' , θ , and the aluminum matrix can all be simply depicted using the fcc cell to describe the aluminum matrix crystal structure (see Table 4). This makes electron scattering from these systems relatively easy to simulate using the multislice formalism^[3] explained earlier in the “The Crystal Structure of Pure Aluminum” section. Figure 17 examines the T_1 phase in Al–Cu–Li alloys where this is no longer the case.

The T_1 phase (nominally Al_2CuLi in composition) has been the subject of considerable uncertainty and debate with regard to its crystal structure.^[225,241,245,259,260,416–423] The most recent structure assessment combined TEM through-focal-series reconstruction with quantitative aberration-corrected HAADF-STEM and DFT to present the most reliable structure for T_1 to date^[260] (see Fig. 17D). The T_1 structure is hexagonal with $P6/mmm$ space group symmetry according to Ref. [260]. These results are closest to the previous X-ray diffraction study by Van Smaalen et al.,^[421] but not in absolute agreement. Precipitates of the T_1 phase form very high-aspect-ratio platelets with major facets coplanar to the basal plane of the hexagonal unit cell that describes the atomic structure of T_1 . These facets are

coplanar to $\{111\}$ in the fcc cell that describes the aluminum matrix. A section through a T_1 precipitate surrounded by the supporting aluminum matrix is modeled in Fig. 17B.

In order to understand the orientation relationship of T_1 with the aluminum matrix and the magnitude of any strain imparted on the matrix by misfit, it is simpler to deal with the aluminum matrix described in terms of the trigonal cell shown in Fig. 17C. In this representation, the small trigonal cell derived earlier in Fig. 3D–F is also shown in relation to the larger trigonal cell derived here. The present cell (dark blue atoms to make it distinct from the previous trigonal cell of Fig. 3D–F) is described in relation to the fcc unit cell of aluminum in the specifications beneath the cell diagram, together with the space group of this larger trigonal cell and all symmetry-independent atom positions.

The orientation relationship of the T_1 structure with this new trigonal cell description of the matrix is such that the a , b , and c axes of one cell are parallel with their counterparts in the other cell. Such a description of the matrix structure facilitates analysis by the multislice approach along the common c axes, which are normal to the T_1 precipitate/Al matrix interfaces. This description and representation of the orientation relationships of the precipitate and matrix structures also allows immediate assessment of the degree of lattice misfit, which is very small (see Table 4).

Most T_1 precipitates are just a single unit cell thick as they strongly resist growth along the c -axis in the hexagonal structure (i.e., $\langle 111 \rangle_{\text{Al,fcc}}$ or $\langle 001 \rangle_{\text{Al,trig}}$). The fit of the T_1 unit cell into the matrix structure shown in Fig. 17E illustrates the equivalence of the a and b lattice parameters for the matrix and T_1 cells and the relationship $c_{T_1} \sim 2c_{\text{Al,trig}}$ with a misfit of 0.9% (see Table 4).

It is worth noting that the T_1 phase in Al–Cu–Li alloys is one of the most efficient strengthening phases in all aluminum alloys.

Other efficient strengthening precipitate phases include the Ω phase, found in Al–Cu–Mg–Ag alloys,^[226,230,231,235,239,245,274] and the S phase, found in Al–Cu–Mg systems.^[229,230,234,239,245,251,252,256,258] Table 4 presents these structures and their orientation relationships and lattice misfits with the most convenient unit cell for describing the aluminum matrix.

In the case of the Ω phase (determined unequivocally by CBED to be orthorhombic^[226]), the most convenient matrix structure description is via the orthorhombic cell derived in Fig. 3G–I. The relationship between this orthorhombic matrix cell and the Ω unit cell, described in Table 4, is $3b_{\text{Al,ortho}} = b_{\Omega}$ and $c_{\text{Al,ortho}} = a_{\Omega}$.

For the S phase, the most convenient matrix structure description is by the large tetragonal cell defined in Fig. 3J–L. The S phase imparts a small amount of misfit strain in the $[100]_s$ direction, almost none in $[010]_s$ and large strain for multiples of c_s that are not multiples of five.

In the analysis of precipitate crystallography, quantitative electron diffraction shows great potential.

Fig. 17 This figure is similar to Fig. 16, except that in this case, a more complex alloy is illustrated. The SSSS (A) shows copper and lithium atoms dissolved in the aluminum matrix (a ternary alloy). Copper and lithium are present at concentrations of approximately 2% and 6%, respectively (i.e., an 8xxx alloy). The T_1 phase is illustrated in part B, after the heat treatment of the solid solution, and it is surrounded by the aluminum matrix which still contains solute atoms but at a much lower concentration. In parts C and D, the structures of the aluminum matrix and the T_1 phase^[260] are compared via the matrix unit cell that is most conducive to such a comparison. T_1 has a hexagonal structure (D), with a basal plane that is coplanar with {111} in the fcc cell of aluminum. It is therefore much easier to describe the aluminum matrix with a trigonal cell (C). The trigonal cell shown in Fig. 3D–F gives rise to the present description, as drawn and described fully here in part C. The cell of Fig. 3D–F is outlined with lighter lines and lighter atoms where they are not shared with the larger trigonal cell described here. The relationships between the matrix and T_1 cells (C and D) in the actual alloy are shown in part E, where it is evident that the lattice mismatch in all axes is very small and therefore imparts almost no volumetric strain within the alloy. This figure was drawn with the aid of VESTA^[1]

Examples of pattern-matching-based quantitative electron diffraction structure determination are sparse and limited to the MSLS approach of Zandbergen, Andersen, and Jansen,^[315,316] also applied in the work of Vissers et al.,^[331] Hasting et al.,^[332] and Holmestad et al.^[339] Although MSLS is a parallel-beam diffraction analysis tool, the same multislice-based approach could be readily applied to CBED patterns collected from individual precipitates, such as the example in Fig. 18.

CBED uses a focused electron probe and is therefore more capable than parallel beam techniques of position-selective probing of nanostructures such as intermetallic precipitates in alloys. CBED also has the advantage that

the reflections possess an intensity distribution over a range of incident angles that reveal the symmetry of the crystal structure along the incident beam direction in a highly visual and easily interpretable fashion. This is not the case with parallel beam diffraction. Not only does CBED allow an immediate *in situ* determination of structural symmetry from the intensity distribution in the pattern,^[226,299] but it has also the capability of constraining pattern-matching refinements of crystal structure and bonding-sensitive structure factors to a level that parallel beam diffraction is incapable of.

The CBED pattern in Fig. 18B was taken through a single T_1 precipitate embedded in an aluminum matrix

Fig. 18 Using CBED to probe and analyze the structures of precipitate phases in alloys. (A) A schematic diagram of electron scattering when the crystal structure of the matrix (aluminum) is interrupted by a precipitate having a different structure. In the present example, a T_1 precipitate is intercepted by the incident and matrix-scattered electron beams. Due to the crystallography of the T_1 phase (see Fig. 17 and Table 4), these beams are scattered at three times as many angles by T_1 as the aluminum matrix (shown only in one dimension in part A to reduce clutter). The resulting experimental CBED pattern (B), collected with 200 keV electrons along $\langle 111 \rangle_{\text{Al,fcc}}$ (or $\langle 001 \rangle_{\text{Al,trig}}$), shows bright reflections at positions three times the shortest scattering vectors in the pattern from the central beam (which floods the center of the pattern). These are the reflections that originate from initial scattering by the matrix before the beam electrons enter the precipitate. All other reflections originate from the T_1 precipitate structure and subsequent rescattering by the matrix below the precipitate. (C) A schematic representation of the specimen in the volume surrounding the T_1 precipitate showing it being sliced into individual atomic planes. This is required by the multislice theory of electron scattering^[3] for a quantitative analysis of the CBED pattern in part B by multislice simulation and pattern matching. The effects of each plane of atoms on the scattering of the electrons is summed up over the entire probed thickness of the specimen in the direction of the specimen normal (coincident with the beam direction and precipitate normal). The precipitate constitutes only a few layers, shown as slices $n + 8$ to $n + 12$ inclusive (C), as it is about 1 nm thick. In contrast, there may be hundreds of slices through the matrix, which can be 50–200 times thicker (only slices n to $n + 26$ are shown here)

in an Al–Cu–Li-based alloy. The $6mm$ symmetry of the pattern is entirely commensurate with the determination of $P6/mmm$ space group symmetry and the structure of Dwyer et al.^[260] The incident electron beam is parallel to the $\langle 001 \rangle$ direction illustrated in Fig. 17 and Table 4.

Figure 18A shows the nature of electron scattering in the present scenario schematically. The incident electron beam diffracts from the simpler crystal structure of the aluminum matrix before all scattered beams are intercepted and re-scattered by the T_1 structure, which has a three-fold larger periodicity in projection in real space than the aluminum matrix. The scattered beams exiting the T_1 precipitate are then further scattered by the matrix below the precipitate. This scenario is illustrated in only one dimension to reduce clutter and simplify the diagram; however, this entanglement process of scattering by the

different crystal structures being probed occurs in two dimensions within the slice approximation used by the multislice formalism.^[3]

The slicing of the probed region along the zone axis and incident beam direction (coincident with the interface normal of the matrix/precipitate/matrix system) is illustrated schematically in Fig. 18C. In practice, the structural model for multislice simulations would consist of many layers of aluminum atoms spanning the total specimen thickness, with a few of these layers replaced by monolayers describing the T_1 atomic structure. The intensities in the CBED pattern are very sensitive to the total thickness as well as the depth of the T_1 precipitate in the specimen. This sensitivity comes from the entangled nature of the scattered and re-scattered beams from each region of the specimen. The perturbation caused by even the thinnest of

precipitates, like T_1 , will be compounded by the subsequent re-scattering by the matrix below the precipitate.

To gain a better understanding of the intensities in the experimental CBED pattern of Fig. 18B, Fig. 19 is presented. Figure 19A shows a schematic representation of the pattern, which has been fully indexed, based on the commensurate matrix and T_1 unit cells illustrated in Fig. 17 and Table 4. This in itself shows the importance of describing the structure of the matrix in a manner that is commensurate with the cell of the precipitate phase because cells that do not have common a and b lattice parameters would require a diffraction pattern to have two sets of indices (one for the matrix cell and one for the precipitate phase cell). In Fig. 19A, the colorations of the symmetry equivalent reflections in the pattern match the colors of the corresponding loci of the lattice planes that give

rise to the reflections, plotted in the c -axis cell projection in Fig. 19B. Figure 19C shows both the T_1 and matrix cells so that the positions of different groups of atoms can be seen in terms of where they lie along the c axes in both cells. Figure 19D–G shows each set of atoms in the T_1 structure and their positions in the a and b axes, projected along the c -axis. Below the structure diagrams, the simulated diffracted intensities from each group of atoms are given. A strong correlation between atomic positions and the strongest intensities contributed to particular reflections is evident. Figure 19H shows how the much shorter periodicity of the aluminum matrix results in scattering by only the $\{300\}$ scattering vectors.

Returning to Fig. 18, the scattering that gives rise to the CBED pattern (Fig. 18B) can be described in the following sequence: prior to intercepting the T_1 precipitate,

Fig. 19 The CBED pattern from Fig. 18B is considered in more detail from the point of view of the atomic structure in this figure sequence. (A) A schematic representation of the pattern (fully indexed according to the unit cell definitions of Fig. 17 and Table 4), with each set of symmetry-equivalent reflections being assigned a color. These colors are repeated for the corresponding lines in part B, which show the positions of the corresponding crystal planes in projection along the c -axis of the unit cell of T_1 (C). (D–H) The different atomic species and their sites in projection along the c -axis are plotted in superposition on the plane locus diagram of part B. Note that in the case of part H, the set of atoms plotted is the projected structure of the aluminum matrix, given in the second trigonal cell shown in part C. Different sets of atoms lie at the intersections of different sets of atomic planes and give rise to different intensity contributions to the reflections in the CBED pattern. The lower halves of parts D–H show simulations of the relative contributions of each set of atoms to a CBED pattern for just a single unit cell in the cases of both T_1 and the aluminum matrix. The intensities correlate with the locations of atoms in specific planes in the structures and allow a CBED pattern (such as the one in Fig. 18) to be inspected and interpreted structurally, in an approximate fashion. The unit cells and their projections were drawn in VESTA⁽¹⁾

the electron beam is only scattered into directions that are linear combinations of the {300} scattering vectors (Fig. 19H). Upon entering the precipitate, each atomic layer scatters every diffracted beam entering the precipitate according to the scattering vectors and relative intensities plotted in Fig. 19D–G. The scattering within the precipitate is any linear combination of the {100} scattering vectors. This triples the number of reflections in all directions. Traveling through the matrix below the precipitate, all of the resultant beams are re-scattered by all linear combinations of only the {300} scattering vectors.

The variations in intensity within the reflection discs in a pattern such as Fig. 18B not only allow the total thickness of the specimen to be measured from the {300} reflections but also allow the depth of the precipitate to be determined quite accurately from all of the reflections in the pattern. In a more approximate fashion, the relative intensities of the reflections in between the {300} reflections are an indication of how strongly the atoms at particular positions are scattering the electron beams. In other words, the average intensities in the reflections are a rough map of atomic mass in the precipitate structure. For example, the pattern in Fig. 18B shows a higher average intensity in the {200} reflections (yellow atomic positions, Fig. 19G) compared to the other reflections (excluding the {300} reflections). This suggests a higher projected atomic mass at the yellow atom positions in the precipitate structure. This may be indicative of a higher copper occupancy at the yellow sites than at the purple sites.

Work is currently under way on QCBED pattern matching of Fig. 18B via the multislice formalism with results yet to be published.

One final tantalizing point to be made about CBED patterns through precipitates having crystallographically coherent interfaces with the surrounding matrix is that although the frequency of the intensity distributions within reflections is indicative of thickness, the shape of the intensity distribution is strongly influenced by the structure factors of the scattering atomic planes. This presents the open question of whether it may be possible to measure bonding effects across the interfaces as well as within the precipitates themselves in a matrix/precipitate/matrix-type CBED geometry such as the one presented in Fig. 18. Work is also currently under way in Al–Cu alloys where QCBED is being applied to CBED patterns taken through θ'' and θ' precipitates within the aluminum matrix. Further discussion of this theme is left for the sub-section on bonding.

Lattice Parameters

Diffraction experiments with both X-rays and electrons have yielded lattice parameters for precipitate phases in aluminum alloys that can be roughly verified by HRTEM imaging or aberration-corrected HAADF-STEM. The work of Dwyer et al.^[260] on the T_1 phase also compares the experimentally measured lattice parameters with the relaxed lattice constants calculated by DFT.

In the case of lattice parameters in alloy structures, the more difficult assessment is associated with the continuous changes in lattice parameter from one position to another in a solid solution. The standard approach for relating lattice parameters to compositional variation within a single-phase material (such as aluminum-based solid solutions in the present context) is via Vegard's law.^[438–440]

Examples from the literature of experimental lattice parameter measurements in aluminum-based solid solutions include very early work on Al–Cu alloys^[441] and investigation of the Ti–Al system,^[442,443] Al–Mn solid solutions,^[444] Al–Zn solid solutions,^[63] and, more recently, the Al–Si–Cu–Mg system with particular attention paid to Al–Mg solid solutions and the aluminum matrix lattice parameter as a function of heat treatment time.^[293] An excellent summary of size factors (lattice parameters) as a function of composition in hundreds of different binary alloy solid solutions is given by King.^[445]

Data mining and semi-empirical methods of modeling lattice parameters in alloy solid solutions are becoming modal via the computer Calculation of Phase Diagrams (CALPHAD) methodology. The semi-empirical models are, at their foundation, based on Vegard's law. Some of the binary solid solutions in aluminum that have been investigated by CALPHAD include Al–Ni,^[446] Al–Li,^[447] Al–Mg,^[447] and Al–Si.^[447,448]

Debye–Waller Factors

The “The Debye–Waller Factor of Elemental Aluminum” section covered the DWF of aluminum atoms within pure aluminum. When aluminum alloys are considered, the environment surrounding each aluminum atom can vary. The thermal vibration of atoms is constrained by the interatomic forces exerted on them in bonding with their neighbors. Thus, an aluminum atom that has a copper atom as a neighbor in a 2xxx series alloy, for example, will have a very different DWF than another aluminum atom in another region of the same alloy where it is surrounded by only aluminum atoms. Because most aluminum alloys are very dilute (in terms of the concentration of alloying elements), most aluminum atoms in aluminum alloys are surrounded by other aluminum atoms as nearest neighbors. As a result, the function for $B(T)$ presented in this work for pure aluminum is valid for these atoms, whereas it is invalid for those neighboring solute atoms or contained within intermetallic precipitates. The work of determining DWFs for aluminum and solute atoms in alloys is limited compared to work in the pure metal; however, it is not insignificant. Examples include Ti–Al,^[449–452] Al–Cu,^[453,454] Al–Si,^[453] Al–Ge,^[453] Ni–Al,^[455,456] and Al–Co–Ni–Fe–Mn–Rh^[457] systems.

The correlation between bond strengths between atoms, and thus mechanical strength, and DWFs is highly intuitive (i.e., the stronger the interatomic bonding, the greater the mechanical strength and the smaller the thermal vibration amplitude or DWF). A strong correlation between

Young's moduli and DWFs has in fact been shown to exist in the limited literature on the subject, which is mainly restricted to elements and simple compounds.^[458–460] This is an area that has not gained much research attention but is well worth exploring in future for more complex systems such as alloy solid solutions and intermetallics.

Bonding

As stated in the “The Bonding Electron Distribution in Aluminum” section, the electronic structure associated with chemical bonding in all materials is the dominant determinant of all materials properties (except radioactivity). Until now, high-resolution bonding studies have been confined to highly pure, homogeneous, and highly ordered crystal structures in relatively simple materials (small unit cells and uniform, stoichiometric compositions throughout the probed material).

The possibility of performing bonding measurements by QCBED in matrix/precipitate/matrix scattering geometries, using the multislice formalism for electron scattering,^[3] has been alluded to already in the discussion of Fig. 18 earlier in this section.

At this juncture, it can be argued that the ultimate resolution to be attained in the crystallography of any crystalline material is the measurement of interatomic bonds. Therefore, the ultimate level of characterization that is to be achieved in aluminum and indeed any of its alloys is to be able to map the bonding structure as a function of position.

Another challenge in canonically describing the structural evolution of an alloy is to accurately and fully understand the processes of nucleation and growth of precipitate phases from solid solutions and all the physicochemical driving forces associated with these processes from the most fundamental denominator, namely, interatomic bonding.

This article concludes with the following conjecture and proposed means of experimentally testing it, which combines the two challenges just described. An electron density domain theory (EDDT) for nucleation and growth of precipitate phases from solid solutions is proposed. This theory is described with the aid of Fig. 20.

It begins with a SSSS where the solute atoms of element *A* are uniformly dispersed in a matrix of element *M*. For the sake of simplicity, a binary alloy is considered. Atoms of element *A* in pure form have a crystal structure with a bonding electron density distribution, which will be correspondingly labeled as type *a*. Pure element *M* that forms the host matrix would have a bonding electron distribution of a different form to type *a*, which shall be called type *m* in correspondence with matrix *M*.

In Fig. 20, the solute atoms, *A*, are shown as red dots dispersed in the blue matrix atoms *M*. Bonding electron density of type *a* is given a red shade, whereas that of type *m* is shaded blue. When atoms *A* and *M* form a precipitate with a particular stoichiometry and structural order, a third

type of bonding electron density distribution exists within the precipitate phase. This shall be called type *p*, and this is given yellow color.

In the initial solid solution (Fig. 20A), bonding type *m* dominates with some mild type *a* bonding having a minor influence due to the generally low concentration of atoms *A* in solution. There will inevitably be regions of slightly higher and slightly lower concentration of atoms *A* in the solid solution, and in those regions of slightly higher concentration, there may be a very weak influence or component of type *p* bonding electron distribution. Increased mobility due to elevated thermal vibration as the temperature is increased during an aging heat treatment can cause the bonding electron distribution to fluctuate. This may be enhanced in the presence of dislocations or lattice defects (not included in the figure), which would cause sharp localized bonding perturbations that may help promote bonding electron distribution type *p*.

In Fig. 20B, the solute atoms *A* (red) are starting to cluster and be driven toward a structural arrangement with atoms *M*, which further promotes bonding type *p*, causing weak domains (surrounded by dashed red lines) of type *p* to form. The influence of this mild type *p* bonding within these domains is to lower the energy barrier for atoms *A* and *M* to form an ordered intermetallic compound.

Clustering then accelerates with the increased mobility of solute atoms at the elevated heat treatment temperature. The increasingly strong type *p* bonding within these domains further accelerates the solid-state chemical reaction that is occurring and provides the driving force underlying the precipitation process. At some point (Fig. 20C), critical nuclei within the ever-strengthening domains of bonding type *p* (outlined with solid red lines and having a strong yellow hue) form the basis of the precipitates with bonding type *p* and stoichiometry of M_xA_y . Within these nuclei, the atomic structure that is commensurate with bonding type *p* and is actually driven to form by bonding type *p* is established and stabilized as a secondary phase in the alloy. The reaction is driven to completion by the self-sustaining process that strengthens bonding type *p*, which provides the driving force for atoms to arrange themselves in the new crystal structure. The reaction stops when the number of solute atoms remaining in the surrounding matrix is too small to sustain the growth of the new phase and, therefore, the extension of the range of influence of bonding type *p* (Fig. 20D).

How could such a theory ever be validated? By “scanning QCBED.” The basis of such a technique is already commonplace. Every time a STEM image is obtained, a focused electron probe or, in other words a convergent electron beam, is rastered across the area of interest of the specimen, and CBED patterns are formed for every probe position spanning that area. STEM detectors integrate over large angular ranges in these CBED patterns to produce a single number, which is the intensity assigned to the corresponding pixel in the STEM image. There is

Fig. 20 A schematic illustration of the EDDT of phase transformation by nucleation and precipitate growth in a binary alloy. (A) A nearly homogeneous solid solution of A atoms (red dots) in a matrix of M atoms (blue). In their pure forms, A and M have bonding electron densities of types “a” (red shading) and “m” (blue shading), respectively. In the solid solution, the superposition of electronic configurations can give rise to other metastable electronic configurations. This figure considers only one such configuration for simplicity, type “p” (shaded in yellow). Slight inhomogeneities present in even the most well-mixed solid solutions cause very weak segregations between different electronic configurations. (B) Heating causes atoms to vibrate with greater amplitude, and this agitates the “electron sea” and causes the diffusion of solute atoms, A (red), toward preferred electronic environments. This in turn results in increased segregation into weak domains of different electronic environments (outlined by the dotted lines). (C) Heating continues, causing the domains of types p and m to strengthen via the migration of atoms into their preferred bonding environments. Critical nuclei of a secondary phase stabilized by the type p bonding environment are formed within the strengthening type p domains. (D) The nuclei grow until almost all of the surrounding solute atoms, A (red), are incorporated into the mature precipitates. During this process, domain segregation approaches completion

a large push in the electron microscopy community for faster detectors with greater electron detection efficiency and faster readout electronics so that the entire CBED pattern can be collected and stored for every point in a STEM image. This, of course, requires many terabytes of storage for a single data set! Some, like the groups of Tsuda^[461] and Zuo,^[462–465] have managed to collect scanning CBED data sets for areas with small scan dimensions (few pixels in the scan) and have used these data sets to obtain position-sensitive information about subtle changes in crystal structure across domain boundaries. The main focus by the groups of Zuo and Tsuda has been the investigation of polarization domains in ferroelectric materials,^[461–465] but scanning CBED combined with QCBED to produce the technique of scanning QCBED or “SQCBED” could be very powerful for analyzing the spatial variations of both atomic structure and chemical bonding as a function of position in many other materials, including alloys.

Here, it is proposed that scanning CBED be applied to SSSSs that are heat treated *in situ* so that scanning CBED data sets are collected for the same region of interest as it is undergoing an artificial ageing heat treatment in a TEM hot stage. This is illustrated in Fig. 21. In the far-left column of Fig. 21, Fig. 20 has been rearranged so that artificial ageing time runs from top to bottom. The color codes of the different bonding types already discussed for Fig. 20 are shown above this sequence on the far left. The column second from the left shows a schematic of the experimental setup in the TEM. Heating coils in contact with the specimen cup heat the solid solution to the required ageing temperature. As ageing progresses in the manner previously described in the discussion of Fig. 20, scanning CBED data sets are collected. Circles in each of the images in the leftmost column of Fig. 21 show the probe positions from which each CBED pattern is collected.

Fig. 21 A schematic illustration of how a new technique that combines scanning CBED and QCED, i.e., “scanning QCED” or SQCED, could be key to validating the EDDT of secondary phase nucleation and precipitate growth. The region illustrated in Fig. 20 is examined here *in situ* (left column of the present figure) while performing a heat treatment that results in the solid solution evolving to form precipitates. Hot stages for TEM are not uncommon, and this allows the heat treatment to be carried out while simultaneously collecting CBED patterns for each position (circled in the images in the leftmost column) in a grid spanning the region of interest. CBED patterns can be collected for an orientation of the incident electron beam which maximizes the sensitivity of QCED to particular structure factors that are most sensitive to the different types of bonding structures that may be present in the specimen. In this illustration, there are three structure factors being measured from each pattern, V_g , V_h , and V_j . These are structure factors of the electrostatic potential and they are directly related to structure factors of the electron distribution, F_g , F_h , and F_j , respectively, via the Mott formula^[194] (note that as the structure factor of the potential increases, the electron distribution structure factor decreases). Each structure factor characterizes a different component of the electron distribution. Maps that associate a different color with each structure factor can be generated from the array of probe positions on the specimen as shown here in RGB format (red for V_g and F_g , green for V_h and F_h , and blue for V_j and F_j). The combination of these components can then be used to map the bonding-type distribution as a function of ageing time and position within the specimen (far-right column)

After the heat treatment and scanning CBED experiment have been run to completion, the CBED patterns can be pattern matched in the usual way of QCBED for very accurate and precise measurements of the relevant structure factors. The incident beam orientation can be set up from the outset to give CBED patterns that are conducive to measuring different components of the bonding electron distribution. These can be color-coded with red, green, and blue such that each structure factor map acts as a color channel for the final image that shows the different bonding modes and their distribution within the region of interest. In other words, the Fourier sum is computed from each color channel as shown.

In this way, the as yet never attempted technique of scanning QCBED is predicted to be the way ahead in expanding the horizons of crystallography in nanostructured crystalline composites such as aluminum alloys.

SUMMARY

This article has taken a hierarchical approach in describing the crystallography of pure aluminum, before bringing the same considerations to bear in the same order on the discussion of aluminum alloys.

The discussion began with a description of the basic form of the structure of pure aluminum and how it can be described by different unit cells. This was followed by a review of as many measurements of the lattice parameter of the fcc cell of pure aluminum as could be found, spanning the full range of temperatures where aluminum is a solid. In combination with an analogous review of linear thermal expansion coefficients across the same temperature range, the related parametrizations of $a(T)$ and $\alpha(T)$ (the lattice parameter as a function of temperature and the linear thermal expansion coefficient as a function of temperature, respectively) were developed as canonical and continuous descriptors of $a(T)$ and $\alpha(T)$ from 0 K to 933 K (the latter temperature being the melting point of aluminum). These parametrizations are intended as a reference for readers who need to obtain accurate values of these physical properties at any temperature where aluminum is a solid. They are supported by, and serve to summarize, a large number of experimental measurements spanning about a century of work.

In the analysis of linear thermal expansion coefficients at high temperatures approaching the melting point of aluminum, a new approach, named here as the “vacancy triangle,” was developed and demonstrated, which allows the vacancy concentration in pure aluminum to be determined with reasonable confidence at temperatures near the melting point of 933 K. In summary, a vacancy triangle is drawn to span the spread of points on a graph of α against T where each α is determined either from length dilation of a bulk sample (affected by vacancies)

or by diffraction (relatively unaffected by vacancies—an approximation in itself). The differences between these two types of measurements as a function of temperature result in a triangular spread of points in a graph of α versus T , and the area spanned by this triangle leads to a measurement of C_{vac} , the vacancy concentration at the temperature that bounds the vertical edge of the triangle in the graph. Using this approach, C_{vac} (927 K) $\approx (1.1 \pm 0.3) \times 10^{-3}$ was obtained, which agrees within the bounds of uncertainty with previous measurements in the literature.

The third aspect of the crystallography of pure aluminum considered was the DWF, B , which quantifies the magnitude of the thermal vibration of the atoms in a crystal. Again, a review of as many published measurements as could be found was undertaken and a parametrization of $B(T)$, valid over the range from 0 to 933 K, was presented. This is intended as a resource for the reader seeking reliable values of B at any temperature where aluminum is a solid. In the process of this review, the shortcomings of other published models and parametrizations of $B(T)$ were discussed, and it was made clear that the present parametrization should be used in preference to that by Gao and Peng^[159,160] which diverges strongly from all of the experimental measurements at higher temperatures.

The discussion of the crystallography of pure aluminum culminated in a review of the bonding electron distribution determinations spanning the past 90 years. Determinations of bonding depend very sensitively on an accurate knowledge of the structure of the lattice, lattice parameters at the temperature of the experiments, and the DWF of aluminium at the relevant temperature, as prerequisites. This defines the hierarchical approach applied in this article, which culminated in determinations of interatomic bonding—the ultimate resolution attainable in crystallography.

In the review of bonding in pure aluminum, it was shown that the technique of QCBED gives the highest resolution and that this technique was pivotal in determining unequivocally that the bonds in pure aluminum are entirely tetrahedral in nature. Before the QCBED study of Nakashima et al.,^[175] there was considerable disagreement in the literature as to the location and nature of bonds in elemental aluminum.

The hierarchical approach developed in considering the crystallography of pure aluminum in the first four sections was applied in discussing the crystallography of aluminum alloys in the last section. Research in the domain of aluminum alloys is vast, and after highlighting a selection of significant papers in each alloy class and summarizing the array of techniques and theoretical approaches used in these works, the discussion turned to specific examples to illustrate the relevance of the concepts discussed in the treatment of pure aluminum in their application to aluminum alloys.

It was shown that describing the structure of the supporting aluminum matrix with an alternate unit cell can greatly simplify the structural modeling of secondary precipitate phases in relation to the surrounding aluminum matrix crystal structure. This was followed by a brief summary of work on determining lattice parameters and DWFs in alloy solid solutions and a discussion of the correlation between DWFs and the macroscopic property of elastic (Young's) modulus.

The correlation between the thermal vibration amplitude of atoms and Young's modulus is highly intuitive and rational, but very little research has been done in relating these properties. It is suggested here that future work should be directed into the exploration of this nano-macro relationship of physical properties, especially for inter-metallic phases and solid solutions. The outcome of such studies would allow the mechanical properties of alloys to be used to estimate DWFs of the constituent atoms. This would supply missing information about DWFs for atoms in different bonding environments, removing a significant obstacle to future planned interatomic bonding studies in alloy systems.

The article ended with the unexplored domain of interatomic bonding measurement in aluminum alloys, introducing a new electron density-based theory for explaining the driving force behind nucleation and growth of precipitate phases from solid solutions (applied in this context to aluminum alloys but applicable to all alloys in general). This is the electron density domain theory (EDDT). In summary, it states that solid-state precipitation reactions are driven by different types of bonding electron distribution that segregate into domains and strengthen within these domains via the migration of solute atoms into favored electronic environments and out of less favorable environments. This process is accelerated by increased thermal vibration (elevated temperature) and is a self-enforcing process. That is, as a domain strengthens in one type of bonding electron distribution, the region surrounding it weakens in that bonding type due to the associated and accelerated migration of atoms to their favored environments.

Finally, an experimental approach was described for testing the EDDT. The method would combine QCBED with STEM, while an alloy solid solution is heat treated *in situ* in an electron microscope. This leaves a vision for the future of crystallographic research in aluminum alloys that would provide fundamental insight into the origins of properties in these extremely important materials.

ACKNOWLEDGMENTS

The author is grateful for funding from the Australian Research Council (FT110100427). The author

is indebted to Prof. J. Etheridge, Prof. B.C. Muddle, A/Prof. L. Bourgeois, A/Prof. M. Weyland, Mr. T. Liu, Dr. Y. Guo, and Mr. D. Peng at Monash University, and Ms J. Shih, formerly at Monash University. The author is also grateful to the staff at the Monash Centre for Electron Microscopy (MCEM) and the Department of Materials Science and Engineering at Monash University. Original work included here was mainly carried out on a JEOL 2011 TEM as well as an FEI Titan³ 80–300 TEM with probe and imaging aberration correctors at MCEM, in combination with a liquid helium specimen stage. The author expresses his thanks to Prof. J.-M. Zuo from the University of Illinois at Urbana–Champaign (UIUC) for long-term collaborations and sharing his *RefineCB* Bloch-wave QCBED code. The author also thanks Mr. Y.-T. Shao, also from the UIUC. Finally, this work would never have been feasible without the immeasurable help and support of Mrs. K. Nakashima.

Appendices

APPENDIX A

Table of experimental and modeled lattice parameters for the fcc unit cell of pure aluminum from the literature.

APPENDIX B

Table of experimental and modeled linear thermal expansion coefficients for pure aluminum from the literature.

APPENDIX C

Table of experimentally and theoretically determined DWFs for pure aluminum from the literature.

APPENDIX D

Table of experimentally and theoretically determined deformation electron densities ($\Delta\rho$) at the tetrahedral, octahedral, and bridge centers in the fcc unit cell of pure aluminum. These are followed by the actual structure factor determinations and associated errors (in the cases of experimental measurements) for the bonding-sensitive structure factors, F_{111} , F_{200} , and F_{220} .

Defects in Aluminum Alloy Castings

John Campbell

Metallurgy and Materials, University of Birmingham, 6 Old Market Court, Market Street, Ledbury, Herefordshire, HR8 2GE, United Kingdom

Abstract

Most of the major defects in Al alloy castings are the result of entrainment processes. The entrainment of the surface of the liquid creates bifilm defects, and the entrainment of air creates bubbles and bubble trails. Occasionally the entrainment of foreign inclusions, such as sand inclusions, can also be a problem. Bifilms form the initiators of gas porosity, shrinkage porosity, hot tears, and cracks. Since bifilms can be controlled by improved melting and casting techniques, all these defects are controllable. In addition, bifilms control the mechanical properties of castings, particularly tensile elongation, toughness, and fatigue. The other important effects caused by bifilms such as invasive corrosion behavior including pitting, stress corrosion cracking, and possibly hydrogen embrittlement, are beyond the scope of this review.

Keywords: Bifilm; Crack; Creep; Entrainment defect; Fatigue; Hot tearing; Inclusion; Porosity.

PREAMBLE

This review “*Defects in Al alloy castings*” was originally to be a review “*Solidification Defects in Al Alloy Castings*.” However, there are few if any solidification defects in cast alloys of any metal. This is because solidification is a phase change involving only minute movements of atoms; the distances that atoms have to move from the liquid to solid states are only a small fraction of an atomic spacing— <0.1 nm. These tiny shuffling movements, reorganising a randomly close packed assembly of atoms into a regular close packed array, are the result of the very similar density of packing of the liquid and solid states, and the consequent very similar interatomic spacings. Under normal conditions, no large void or crack can appear because the bonds between the atoms are immensely strong; the atoms remain densely packed during the entire process of solidification.

It is important to keep in mind that the tiny atom movements in solidification result in the formation of second phases and intermetallics which have perfect atomic contact with the matrix. Cracks cannot be formed. In addition, stresses generated during freezing are far too low to create cracks. Thus, the very common appearance of cracked particles on polished micrographic sections has to have another explanation; the particles have nucleated and grown on bifilms in the melt. This important mechanism will be considered in detail later.

Following this line of thought further, it has been supposed that voids can be opened up during solidification because of either

1. The presence of gas in solution in the liquid metal. If the gas is less soluble in the solid metal, then the rejection of this solute at the advancing solidification front might lead to such a supersaturation of gas that the gas may precipitate as bubbles.
2. The generation of stress as a result of solidification shrinkage (the volume change on freezing).

Both of these possibilities have been studied many times in many different ways. In brief, the consensus is that neither is possible when considering the nucleation of a volume defect from an embryo pore of atomic size (a pore effectively consisting of a few vacancies or a few atoms of gas). The nucleation conditions (stress or gas supersaturation) are far too difficult to meet under normal circumstances.^[1]

The impossibility of classical homogeneous nucleation as an atomic-sized event is a result, once again, of the very strong bonds between atoms. Such an event can be generated, but the stress involved to “fracture” liquid aluminum is in the region of 10 GPa. This is the ultimate “strength” of the liquid and is so high that it can never be reached during normal solidification conditions.

When attempting to define the most severe stresses in a solidifying casting, the shrinkage conditions in a liquid, trapped inside a solidifying sphere, were first explored by Campbell^[2] using an elastic/plastic model. Internal stress was high in the residual, contracting liquid, but only of the order of 100 MPa, a factor of 100 times too small to nucleate a cavity. This estimate was later confirmed by a creep-based model^[3] so there is some reason to believe it

represents a fair estimate of the upper limit to the stress in a solidifying casting. However, this high upper value has been shown to be reduced by thermal contraction^[4] and by buckling effects^[5] as discussed further below.

SURFACE SINKS (SOLID FEEDING)

In practice, buckling is commonly observed in Al castings in the form of surface sinks (sometimes called “draws”) on the outside of the casting. It represents a kind of exterior form of shrinkage porosity, often reducing internal stress so that internal defects are avoided. Surface sinks are common in Al alloy castings because of both the low strength of the alloy, particularly at its freezing point, and its high thermal conductivity, which ensures the surface temperature remains high, close to that of the interior. (These conditions contrast with steels, in which surface sinks are not common because of poor thermal conductivity, so the surface can become significantly colder, gaining more of its already high mechanical strength to resist collapse, and thereby support larger internal stresses.)

The manipulation of surface sink effects to eliminate internal porosity in Al alloys is a valuable technique. It has been called “solid feeding” in contrast to the more normal technique of “liquid feeding” to counter the formation of internal shrinkage porosity. If the surface sink is not severe, or is encouraged to be more widely distributed, it is often not outside the dimensional tolerance limits for the casting and may even be not noticeable or even detectable. A tiny surface movement will eliminate a significant internal pore. For instance, liquid Al contracts approximately 7% on freezing. A 100mm sphere of metal would therefore produce either a central hole 40mm diameter, or a surface contraction of 1.2mm. Spreading the volume contraction over the large external surface is an excellent way to reduce internal porosity.

To gain fully the benefits of solid feeding, it is necessary to avoid easy initiation of porosity inside the casting. This is achievable by eliminating the easy initiation sites—the bifilms. We shall deal with this problem later.

ENTRAINMENT DEFECTS

Over recent years, it has become increasingly clear that the stirring and pouring of liquid metals can entrain serious defects. The defects include bifilms, bubbles, and external (entrained) foreign inclusions.^[6] Considering these in order:

Bifilms

In steel castings, it has been found that 98% of inclusions are entrainment defects resulting from taking down the surface oxide on the liquid, together with air, into the bulk

liquid. In Al alloy castings, it seems likely that similar, disproportionally large amounts of entrained defects will dominate the total count of inclusions.

Formation of Bifilms

The entrainment of the surface oxide during stirring or pouring can introduce thousands of bifilms into the liquid. Whenever a splash or droplet of liquid metal impinges on another splash or droplet, their surface oxides meet dry-side to dry-side (Fig. 1). Similar encounters occur during simple folding of the surface.

In a larger body of liquid, such conditions can occur when the dimensionless parameters, Weber number (We) or Froude number (Fr), are greater than unity.^[6] Weber number assesses the balance of surface tension and inertial forces in the liquid, and so assessing the stability of capillary waves. Fr assesses the balance between gravity and inertial forces at the surface of the liquid, and so is relevant to larger scale gravity waves, seen as slopping and surging effects. In either case, a value above unity indicates the surface may become unstable, suffering breaking waves, in which the surface film is once again folded into the bulk liquid. The $We = 1$ condition corresponds to the critical velocity in the region of 0.5 m/s for most liquid metals, at which entrainment of the surface becomes possible. This value is used as a critical velocity not to be exceeded anywhere during processing or casting of liquid metals, and especially at the ingate into a mold cavity. Speeds above this value are in danger of jetting and jumping, and so in danger of entraining the liquid surface to entrain bifilm defects.

When first entrained, the turbulence in the bulk melt (under the surface, which might be relatively tranquil) will cause the bifilm to ravel into a fairly compact ball. In this way a bifilm of 10mm diameter might be reduced to

Fig. 1 The entrainment of the surface oxide and air during turbulent folds and splashes of the liquid metal. The entrained oxides survive as double films (bifilms) decorated with bubbles of various sizes. The buoyancy of larger bubbles may assist them to detrain

a tangled ball only 1 mm or so in size. In this form, it is relatively (but not completely of course) harmless from the point of view of being a damaging crack. Its ravelled crack morphology is a defect structure unique to liquid metals.

Later, during solidification, the compact convoluted bifilm may be straightened. Various mechanisms are active, assisting to straighten the bifilm. All the methods take time.

The mechanisms for the straightening of originally convoluted bifilms include (i) gas precipitation that inflates the bifilm, (ii) shrinkage that can act similarly, (iii) dendrite pushing, and (iv) flattening by the attachment of strong, straight-growing second phases and intermetallics for which the bifilm and new phase adhere strongly.

In this way mechanical properties that are originally reasonably high when first cast gradually deteriorate, as the clouds of bifilms gradually evolve from fairly harmless, compact, and ravelled features into serious flat, engineering-type cracks. This is the reason for good properties in chilled material, but poorer properties in heavy sections (the effect of the Hall–Petch relation is relatively minor).^[6]

Properties of Bifilms

Bifilms consist of two oxide films, with their dry, unwetted surfaces facing. The absence of any significant bonding between this pair of films allows the bifilm to act as a crack.

In contrast, the outer surfaces of the bifilm are the original undersides of the oxide films grown on the liquid metal. The growth process of the film, atom by atom, naturally results in these outer surfaces of the bifilm being in perfect atomic contact with the liquid. Effectively, they are perfectly “wetted.” These exterior interfaces appear to act as substrates for the formation of every second phase and intermetallic compound that has been checked so far. The reader should beware of loose and imprecise language such as “Brittle grain boundary phases” when many phases are actually ductile, but their brittle appearance results from apparent cracks resulting from the phase having grown on a bifilm.^[7] The bifilm may or may not be visible depending on whether some gas absorption or mechanical strain has occurred to separate its halves.

The density of aluminum oxide (alumina, Al_2O_3) is higher than the liquid, and so it might be expected that the bifilms would sink. However, when first entrained, a high proportion will have air trapped between the films in the surface roughness of the oxide and in the folds and creases of the two films. Thus, initially, most of the bifilms will float. The entrapped air inside the bifilm is subsequently consumed by the thickening of both of the films, using up first the oxygen to make more oxides, and when that is all gone, using up all the nitrogen to make nitrides. When most of the air is consumed, the bifilms will tend to sink. All this takes time, and any hydrogen in the alloy will tend to keep the bifilms in suspension. Depending on

the circumstances, gradual sedimentation of bifilms in Al alloys can therefore take minutes, hours, or days. (Again, bifilms in steel behave differently, being very different in density, so that most bifilms tend to float out within minutes, leaving the steel clean—even though, of course, very fine bifilms will be expected to be slower to escape).

The rate at which the oxygen and nitrogen from the air is consumed by the thickening of the films of the bifilm has been measured in interesting experiments by Raiszadeh and Griffiths.^[8] These times range between a few minutes and an hour, but the total gas in the bifilm may or may not reduce as a result of hydrogen diffusing in. The presence of hydrogen is therefore a large factor in retaining bifilms in suspension in Al alloys.

In addition, air contains 1% argon that is inert and insoluble in liquid metals. As an example, a 100 μm diameter air bubble will gradually shrink down to a 3 μm diameter bubble of argon, but no further. The argon bubble plus its surrounding array of oxide films, which are the remnant of the original air bubble, will be a permanent feature of the alloy. With its residual argon, the bifilm will never completely disappear nor be completely welded closed, despite any amount of plastic work by forging or rolling, etc.

Effect of Bifilms on Microstructure

The formation of intermetallic compounds on bifilms is most clearly revealed in the formation of βFe precipitates in Al–Si alloys (Fig. 2). This compound has a monoclinic lattice structure which encourages its growth as thin, straight plates (appearing as needles in 2-D). Since it forms preferentially on bifilms, it often exhibits a central crack along the length of the needle. The extremely effective way in which bifilms are flattened by βFe is the reason why iron

Fig. 2 An Al–11Si alloy, containing beta-Fe and silicon particles formed on bifilms, which have been straightened during the growth of these adherent planar crystals. The bifilms have been opened to reveal their crack-like form by a transverse tensile strain

is the most damaging impurity element in Al alloys; it creates a compound of relatively large volume compared to its Fe content as a result of incorporating Si and much Al (its formula is Al_5FeSi), and it is impressively effective in converting convoluted compact bifilms into straight cracks to maximize their damage to properties.

In Al-Si alloys, silicon also grows on bifilms, straightening them, and thus forming the primary Si flakes that are the basis of the so-called unmodified Al-Si structure (Fig. 2). Naturally, the straightened bifilms within the Si particles impair the mechanical properties. The addition of Sr to modify the eutectic Si deactivates the bifilms as substrates for Si. Now, no longer able to precipitate and grow easily, the liquid alloy now continues to cool, finally nucleating Si, which now grows cooperatively with Al in a classical, coupled eutectic. The Si now takes the form of continuously advancing and branching coral, not relying on any bifilm mechanism for growth; its fine spacing is controlled by diffusion in the liquid. We call this structure “modified.”

Bifilms also appear to control the texture of worked Al alloys. In the liquid state, bifilms tend to be pushed by advancing dendrites and grains, and so often come to rest in grain boundaries. Similarly, during the plastic deformation of alloys in the solid state, the recrystallization and grain boundary migration will occur until the boundary encounters a bifilm. At that point, the boundary movement is arrested because the boundary cannot cross the “air gap” between the films. As a result, a high proportion of bifilms are coincident with grain boundaries.

The pinning of boundaries by bifilms is probably the major effect in the development of textures and elongated grains during plastic deformation (since otherwise, recrystallization and uninhibited grain growth would have led to an equiaxed structure to minimize grain boundary energy). The strong effect of the presence of oxides is most clearly seen in the many results on the lamination of different materials to make a single rolled product where the original oxide double film at the junction between the two materials forms an impassable barrier to grain boundary migration.

Many of the features for which grain boundaries are known, such as the way in which second phases tend to form there, may not be the result of the simple energy saving assumed by traditional thinking, but may be the result of the presence of the bifilm. There seems to be some evidence that many grain boundary precipitates would not occur if the boundary did not contain a bifilm. At least part of this effect may be the reduction in strain energy of the formation of the new phase, because its volume change and/or shape change can be more easily accommodated by the presence of the “air gap.”

Effect of Bifilms on Other Defects

Entrainment defects, particularly bifilms and bubbles, appear to be the fundamental casting defects from which

practically all other casting defects originate. Most casting defects require to be nucleated, or, more accurately, need to be initiated (since the initiation mechanism is not an atom-scale process, but a mesoscale, or even macroscale process, as will become clear).

Porosity Al alloy castings are renowned for their porosity problems. This is partly the result of

1. Its freezing contraction is 7%, which is the highest for any metal.
2. Its high hydrogen solubility of the liquid and the low hydrogen solubility of the solid, in a ratio of approximately 20 to 1, which is, once again, one of the highest differences among the engineering metals.
3. Its dense population of oxide bifilms, whose nearly neutral buoyancy keeps them in suspension for longer periods than any other liquid metal.

It follows that hydrogen porosity can be reduced by reducing hydrogen (of course!) but can also be reduced by reducing the bifilm initiators. As mentioned in Section “Bubbles,” the fine (<0.5 mm diameter) hydrogen pores, usually nicely dispersed but often with some concentration adjacent to the surface (often known as subsurface pores) are quite different to the large, generally clustered pores up to 5 mm diameter which are air bubbles trapped under the oxide skin of the casting.

Hot Tearing There is a legion of tests for hot tearing susceptibility, which have identified that the most susceptible alloys have a thin liquid film which appears to separate the grains of the metal. The continued existence of this thin liquid film over a range of decreasing temperature means that the film will be subject to increasing tensile strain, so that any local drainage of the film will constitute a tensile failure.

It seems that this process has to be initiated. This could be viewed as a surprise, since the question arises “why does the drainage not initiate at the surface of the casting, which will involve merely a sucking inward of air to form the crack or hot tear.” It may be that in general the oxide film on the casting surface prevents the withdrawal of the liquid from the surface. This would happen if the oxide were in perfect atom contact with the liquid, which is to be expected. The distance between grains or dendrites across which the oxide film would have to support the inwardly deflecting liquid is sufficiently short that large tensile stress in the liquid would probably be resisted without problem.

If initiation of the tear cannot occur from the surface of the casting, then it has to occur inside. Once again, the obvious candidate is a bifilm because of its two films being separable with minimal difficulty. Also, of course, those tears apparently initiated from the surface of the casting are most probably the result of the emergence of a bifilm at the surface (rather than the surface oxide of the casting being breached).

This conclusion matches experimental results on the shop floor of foundries. There is now plenty of experience that hot tears can be immediately eliminated by careful attention to the design of the filling system for the casting. The elimination of turbulence in the running system automatically eliminates hot tears.

It is curious that tests for hot tearing continue to multiply in the research literature. However, it is interesting that, without exception, all are characterized by a poor filling system design. If they were provided with a well-designed filling system and provided with a good quality melt (i.e., low in bifilm content), it is certain that the hot tearing tests would never exhibit another tear.^[6]

Cracks The elimination of a poor filling system design also eliminates cracks in castings, exactly analogous to the elimination of hot tears.

Effect of Bifilms on Properties

For about a decade, there has been a controversy concerning whether pores or bifilms are more damaging to mechanical properties. For instance, pores might not be expected to be as serious a defect as a bifilm because of its rounded shape compared to the sharp notch provided by the bifilm. Nevertheless, the large majority of studies have shown a direct correlation between pore size and mechanical properties and have naturally concluded that pores are more important than bifilms in initiating cracks. On reflection, this conclusion is perhaps not so surprising. In fact, pores would always be expected to be associated with a bifilm, so that part of the pore circumference would be expected to have a piece of bifilm poking out which would greatly assist the pore to initiate a crack. The nanometer thickness of most bifilms would ensure that they remained unnoticed.

Tensile Properties

The low elongations typical of many cast aluminum alloys, in the region of a few percent, are convincingly raised to values in the range 12%–20% by simple steps to lower bifilm populations, combined with good casting techniques that avoid reintroduction of bifilms into the casting during pouring.

Conversely, the yield strength of Al alloys is not significantly affected by moderate pores or cracks. This is because the negative aspect of the loss of area to support the stress is countered to some extent by the additional strain on the surrounding matrix, which then benefits from the additional strength due to work hardening.

Tensile strength suffers from bifilms and pores because of the early linking of defects, reducing the elongation to failure, and so reducing the possibility for the alloy to gain strength by the accumulation of work hardening over a longer period of extension prior to failure.

Fatigue is impaired because of the ease of initiating the fatigue crack. In fact, the number of cycles required for fatigue crack initiation is zero, because, of course, the crack preexists. In addition, the linking of a dense population of bifilms in the path of the crack is also expected to increase the rate of propagation of the fatigue crack. The excellent relation between elongation and fatigue corroborates the bifilm mechanism.^[9]

There appears to have been no research to date to explore the possibility that creep rate increases with bifilm content. However, the link between the creep behavior of single crystal turbine blades indicates a strong correlation between entrained defects and creep resistance.^[10] Following the confirmation over recent years that grain boundaries are immensely strong, the argument for failure at “weak grain boundaries” to explain the benefits of the single grain is clearly not valid. The benefits of the single crystal appear instead to be the result of its comparative freedom from bifilms. More study of this phenomenon would be welcome.

Bubbles

Bubbles entrained in the metal stream during pouring tend to float out early, prior to any solidification. Large bubbles, unless trapped by cores or other obstacles, are quickly able to escape by bursting at the upper surface of the casting, because they have sufficient buoyancy to break their own oxide skin, and the oxide skin on the top surface of the casting, thus releasing their contents to the permeable mold or the atmosphere. Bubbles smaller than about 5 mm diameter have insufficient buoyancy to break this double film at the top of the casting, and thus remain trapped just under the oxide skin.

These bubbles, all usually <5 mm diameter, are often called “gas” defects. However, they are simply air bubbles introduced by turbulence in the running system; degassing will not remove them!

Whether the bubbles escape or are trapped, they will all have originally had an oxide bubble trail attached. This is because the bubble can only rise through the metal by bursting its oxide film at the crown of the bubble. This oxide slides around the circumference of the bubble, coming together under the bubble as a collapsed oxide tube. Occasionally, severe turbulence can break the trail, releasing the bubble to rise unhindered. Bubble trails are a severe defect in castings, acting as a kind of elongated bifilm crack, and at the same time can form an excellent leak path from the bottom to the top of the casting.

The emergence of a bubble trail near the top of a casting is often clearly seen in a dye penetrant test. The trail, as a long tube penetrating deeply into the casting, can absorb a large quantity of dye, giving a deep red circular indication. This is quite distinct from the faint pink linear indications created by bifilms, as closed, or nearly

closed cracks, decorated with tiny pockets of entrapped residues of air.

The 5 mm diameter air bubbles contrast with fine pores usually <0.5 mm diameter that is hydrogen porosity. These fine pores are formed by hydrogen diffusing into bifilms and expanding the central unbonded space between the films. Because the density of bifilms is usually large, the density of hydrogen pores can be high: 10 pores per square centimeter can easily rise to much higher values against cores, where there is more time for hydrogen to diffuse into and inflate bifilms. Naturally, this variety of porosity formed on bifilms can be reduced or eliminated by not only reducing hydrogen content in the metal but also by reducing bifilm content.

Foreign Inclusions

The foreign inclusions in cast metals are relatively rare, being usually only 1% or 2% of the total number of inclusions. Because this variety of defect is relatively rare, we will only consider one of the most common examples: the sand inclusion in sand castings.

Sand Inclusions

Sand inclusions are entrained only when the melt is turbulent and entraining air. These are relatively common, but seriously bad filling conditions for castings. The hot melt heats the surface of the mold as it splashes backward and forward in an oversize sprue. The air, alternately pushed in and out of the mold surface as the metal stream rattles back and forth, quickly oxidizes away the binder. The successive impacts of the stream on the sand, now unbonded, releases sand into the stream. The sand enters the metal (i.e., is entrained into the metal) wrapping itself in the surface oxide as it passes through the melt surface. All sand inclusions are therefore found wrapped in their “paper bag” of oxide film.^[6] Sand inclusions are a reliable sign of a poor, turbulent, filling system design (almost never the result of poor sand binder quality).

CONCLUSIONS

The action of entrainment during the turbulence of casting create defects, particularly bifilms, which appear to be the fundamental defect required for the initiation of all other volume defects (porosity, hot tears, and cracks) observed in castings and the fundamental defect controlling mechanical properties including strength, elongation, fatigue, and creep.

This review does not include some of the effects of the bifilm population on corrosion properties and the properties of wrought Al alloys, such as the control of the development of texture, toughness, fatigue, and invasive corrosion such as pitting and stress corrosion cracking.

Abstract

A large proportion of all aluminum alloys are used as rolled products in the form of sheet, foil or plate. In virtually all cases, the required properties of these materials are specific to the application such as microstructure, and thermal and mechanical properties. This article describes the fundamental relationship between composition, rolling process, microstructures, and properties and illustrates how rolling processes can be designed to achieve optimal application specific properties.

Keywords: Homogenization; Hot rolling; Recovery; Recrystallization; Textures; Work hardening.

INTRODUCTION

A large proportion (~50%) of all aluminum alloys are used as rolled products in the form of sheet, foil, or plate for an increasingly wide variety of applications. Over the last few decades, there has been a strong development of aluminum sheet and foil for the packaging industry, typically for beverage cans, foil containers, and foil wrapping. The building industry is now also a major user of sheet for roofing and siding, whereas the transport industry, one of the first to use aluminum alloys, is an expanding market for strong, light alloys; both sheet and plate are used for aircraft construction, ships, high-speed trains, and military vehicles. In this context, the high-volume production of lighter automobile frames and body parts in aluminum is now expected to become a major feature of the drive to improve fuel consumption and to reduce gas emissions. Finally, a small but significant part of the foil material is used in specialized “niche” markets such as electrical equipment, heat exchangers, and lithographical plates.

The alloys are used essentially because of their overall combination of lightness, conductivity (electrical and thermal), corrosion resistance, machinability, and a wide range of mechanical strengths. Other important properties such as formability and weldability vary significantly with the composition and the processing method. The reader will find a number of useful descriptions of alloys,^[1] metallurgy,^[2] and processing routes.^[3,4]

In virtually all practical cases, the required properties are tailored to a particular application by a close control of their microstructures via their composition and the

thermal and thermomechanical treatments. Rolling, as one of the most important solid state processing routes, is obviously a thermomechanical treatment that offers considerable potential for microstructure control. If, traditionally, rolling has been used to transform the material shape, for example, from ingot to sheet, then it has also become a cost-effective process for microstructure control and property improvement. A well-known example is the breakup of the as-cast structure and the refinement of grain size.

In more detail, the microstructural variables for a given composition are grain size, shape, and orientation (or macroscopical texture); the deformation substructures are subgrain size and dislocation densities, and, of course, the second-phase particle distributions (size, shape, and spatial distributions). These variables influence the mechanical strength, ductility, and anisotropy of the product (i.e., most of the critical properties for important industrial applications). They depend on the composition of the alloy and the thermomechanical treatments, sometimes in a rather complicated way.

The aim of this chapter is, first, to describe the basic relations between composition, rolling process, microstructures, and properties, and, second, to illustrate how rolling processes can be designed to achieve optimal properties for specific applications.

TYPICAL ALLOYS AND PROPERTIES

Pure aluminum is a light (relative density 2.7 g/cm³) but very soft metal only used for specific electronic applications. It is usually alloyed (with Mg, Mn, Si, Zn, Cu, etc.)

to develop mechanical strengths (UTS) ranging from 50 to 650 MPa. The most common types of alloys that undergo rolling are given in Table 1.

More specific examples of the compositions and properties of some well-known alloys are given in Table 2.

For a given alloy, the properties obviously depend on the metallurgical state of the material as classified by the characters O , $H(x)$, and $T(x)$. It is recalled that O refers to the annealed (i.e., soft and ductile) condition, H is for a work-hardened state, typically cold-rolled, and T denotes the tempered condition (i.e., solutionized and aged for precipitation hardening). The reader is referred to Ref. [1] for further details of the nomenclature concerning alloys and their treatments.

Very schematically, foil material is made from the 1xxx (and 8xxx) series for packaging; most sheets are from the work-hardened alloys (3xxx, 5xxx; for can stock and vehicle bodies) and most plates are from the high-strength 2xxx and 7xxx age-hardened alloys for aircraft, aerospace, etc.

ROLLING SCHEDULES

Most aluminum alloy ingots are produced by direct chill (DC) semicontinuous casting with typical dimensions of 0.4–0.6 m thickness, 2 m width, and up to 9 m length (weight, 20–30 tons). These ingots are destined to be rolled

Table 1 Generic aluminum alloys, properties, and applications (minor elements in parentheses)

Series	Major alloying elements	UTS [MPa]	Major applications
1xxx	<1% (Fe + Si)	50–150	Cooking utensils, heat exchangers, packaging foil, electrical conductors
2xxx	2–6% Cu (+Si, Mg)	300–480	Sheet and plate for aerospace, armaments, general mechanical engineering
3xxx	0.5–1.5% Mn (+Mg, Cu)	100–240	Packaging, can stock, cooking utensils, car radiators, construction
5xxx	0.5–1.5% Mg (+Mn, Cu)	100–340	Construction, ship building, cars, trucks (sheet panels), can ends, wire
6xxx	0.5–1.5% Mg + 1–2% Si (Cu, Cr)	200–400	Mostly extrusions but rolled sheet for transport
7xxx	5–7% Zn + 1–2% g (Cu, Zr)	320–650	Aerospace, mechanical construction, sport and leisure equipment
8xxx	>1% (Fe + Si)	130–190	Packaging foil, heat exchangers

Table 2 Some specific alloys, treatments, and properties (Typically 2–4 mm sheets)

Alloy	Composition [wt.%]	State	YS [MPa]	UTS [MPa]	Elongation [%]
1050A	0.2Si, 0.4 Fe	O	35	90	40
		H14	115	125	20
2024	3.8–4.9Cu, 1.2–1.8Mg (Mn, Si, Fe)	O	140	220	13
		T4	275	425	14
		T8	400	460	5

		T6	470	540	7

down to plate, sheet, etc., by a rolling schedule comprising hot rolling, cold rolling, and often intermediate anneals, as detailed below.

Homogenization

The ingot is first homogenized (i.e., heated to a temperature in the range 500–600°C) for relatively long time (at least a few hours) to reduce segregation and to remove non-equilibrium, low-melting point eutectics. This facilitates subsequent hot working and improves homogeneity. The homogenization treatment can also have a further effect on the final microstructures of some alloys in that precipitation reactions can occur during the treatment. For example, the high-strength 7xxx alloys containing Mn or Zr tend to precipitate out submicron particles (dispersoids) of Al_6Mn or Al_3Zr during the heating up stage. These dispersoids are very stable and can strongly influence the recrystallization behavior, and thereby the grain size and structure.

Hot Rolling

After homogenization, the ingot is usually hot-rolled down to a 30- to 10-mm-thick strip in a reversible (breakdown) rolling mill (Fig. 1). The number of passes varies from 9 to 25. The strip from the single-stand breakdown mill is either coiled to await cold rolling or, in modern processing lines, further hot-rolled in a multiple stand tandem mill. Figure 2 illustrates a conventional reversible three stand tandem mill set up. In current practice, the tandem mills have between two and six stands.

Cold rolling is usually carried out in a reversible cold mill between two coilers, as shown in Fig. 3. When correctly set up, this equipment can be used to roll down the “softer” alloys to a thickness of 15–20 μm . To obtain a very thin packaging foil of about 6 μm in thickness, the foils are then doubled up and rerolled. Intermediate annealing is frequently necessary to achieve large cold rolling reductions.

It should be noted that an increasing proportion of the less strongly alloyed sheet products are now produced by continuous strip casting methods. As shown in Fig. 4, the

Fig. 1 Schematic of reversible breakdown rolling mill^[3]

Fig. 2 Schematic of reversible and (three-stand) tandem mill setup^[3]

Fig. 3 Schematic of cold rolling mill^[3]

Fig. 4 Schematic of continuous strip casting^[3]

hot metal is poured between rotating cylinders to produce a “thick” sheet (10–20 mm), which is then immediately rolled in a tandem mill.

Rolling Conditions

Table 3 indicates some typical dimensions and temperatures for the different rolling processes. Figure 5 also shows typical temperature/time schedules for the production of (a) can stock and (b) foil. Close microstructure control requires knowledge of the average and local strains, strain rates, and temperatures as a function of time, together with the interpass times for a given pass.

The values of these parameters should then be evaluated throughout the entire rolling schedule.

The average deformation per pass is given by the thickness reduction $h_0 \rightarrow h$ as $\epsilon = \ln h/h_0$ and the corresponding average strain rate $\dot{\epsilon}$ is obtained by dividing by the pass

Table 3 Some typical rolling conditions

	Reversible	Tandem	Cold rolling
Start temperature [°C]	500–600	400–500	20
Finish temperature [°C]	400–500	250–350	100
Number of passes	9–25	2–5	2–10
Initial thickness [mm]	400–600	45–15	2–6
Final thickness [mm]	45–15	2–9	0.01–1
Strain per pass	0.1–0.5	0.7	0.3–0.7
Total strain	3.5	3	<5
Strain rates [sec ⁻¹]	1–10	10–100	>50
Inter-stand times [sec]	10–300	<5	

**Fig. 5** Two typical temperature/time schedules for the production of (a) can stock and (b) foil

time. It is now becoming standard to use the more general description of strain (and strain rate), that is, the von Mises equivalent strain defined as $\bar{\epsilon} = \sqrt{2/3 \epsilon_{ij} \epsilon_{ij}}$ (or strain rate $\dot{\bar{\epsilon}} = \sqrt{2/3 \dot{\epsilon}_{ij} \dot{\epsilon}_{ij}}$ adopting the repeated indices summation convention. To a very rough approximation for macroscopical sheets, rolling deformation is plane strain compression for which the transverse strain is zero and the averaged shear components are taken as zero so that, in terms of strain rate components:

$$\begin{aligned} \dot{\bar{\epsilon}} &= \sqrt{\frac{2}{3} (\dot{\epsilon}_{11}^2 + \dot{\epsilon}_{22}^2 + 2\dot{\epsilon}_{33}^2 + 2\dot{\epsilon}_{12}^2 + 2\dot{\epsilon}_{13}^2 + 2\dot{\epsilon}_{23}^2)} \\ &= \frac{2}{\sqrt{3}} \dot{\epsilon}_{11} \end{aligned} \quad (1)$$

The real instantaneous strain rates depend on the geometry of the rolls, and the work piece and the friction conditions between them. They vary through the roll bite and also from the surface to the center. For cold rolling thin sheet, the deformation can be considered close to plane strain compression as assumed above. However, for hot rolling of thick plates, there are significant redundant shear deformations through a large part of the thickness. The metal roll contact zone for this situation is illustrated schematically

in Fig. 6; only at the neutral point is the local metal velocity exactly equal to that of the rolls. Before the neutral point, the metal advances more slowly than the rolls and, after the neutral point, it exits more quickly; the difference gives rise to additional shear components whose sign changes during the pass and which can be large near the surface. The exact evaluation of the local deformations during the

**Fig. 6** Schematic of metal roll contact zone during hot rolling of thick plate. The neutral point is situated at an angle ψ to the vertical

Fig. 7 The cumulated shear and compression strain components through the roll gap of a breakdown mill, at two depths (a, b, near center; c, d, near surface), and for two passes (strain rate and temperature fields calculated by finite element methods for a 3104 alloy in the stationary regime)^[5]

process has been the subject of much research. Approximate solutions are obtained by slip line theory, but most of the recent analyses adopt finite element methods (FEMs).

Figure 7 gives some finite element results for the cumulated shear and compression strain components through the roll gap of a breakdown mill, at two depths in the sample and for two passes (strain rate and temperature fields calculated for a 3104 alloy in the stationary regime^[5]). In the first passes, the (negative and positive) shear terms are roughly equivalent so they balance out, whereas during the later passes, the small initial negative shear is more than compensated for by the large positive shear at the exit. Note also that there are temperature variations in the metal (on the order of 10–20°C) between the surface and the hotter center.

MICROSTRUCTURE-PROPERTY EVOLUTION

Work Hardening

As seen above, many alloys are used directly in the work-hardened state, so their work hardening characteristics are a major issue. Work hardening is also important in a more indirect way because of its influence on both formability and subsequent softening processes such as recrystallization.

The role of work hardening during forming is well known because, according to the Considere criterion, the

limiting strain for homogeneous deformation is given by the work hardening coefficient n ; this is a major advantage of the Al–Mg alloys that possess relatively high n values.

The role of work hardening on microstructure evolution is critical for subsequent softening by annealing to enable recovery or recrystallization; in many practical cases, this occurs during cooling after hot rolling, so the hardening and softening phenomena during hot working strongly influence the final structure. Finally, they also control the loads required during the rolling process for metal deformation. Concurrent softening during high-temperature working is, of course, the fundamental reason for carrying out hot rolling.

The work hardening of a metal is usually represented by the flow stress σ and its evolution during deformation (i.e., $d\sigma/d\varepsilon$ or $d\sigma/dt$). A general stress is described by the Cauchy stress tensor $[\sigma]$, which is often reduced to a scalar equivalent stress or von Mises stress $\bar{\sigma}$, defined in a similar way to the equivalent strain (Eq. 1). During plastic strain, this equivalent flow stress is identical to the flow stress of a material as measured during a standard, uniaxial, tensile test.

Cold Deformation

Work hardening will be described initially for the temperature ranges where thermally activated processes do not play a significant role (typically for homologous temperatures

below $0.4T_m$ or $\sim 100^\circ\text{C}$ for Al). At these temperatures, material viscosity effects are negligible so that, for example, plastic behavior is independent of the strain rate. One can then define a unique yield stress σ_y , the stress at which plastic flow begins. Figure 8 illustrates some typical room temperature stress-strain curves for Al-Mg alloys. Clearly, these alloys exhibit high work hardening rates with flow stresses evolving from ~ 100 to ~ 400 MPa (and even higher during cold rolling).

Macroscopical Laws Stress-strain curves are sometimes represented by the simple Ludwik power law:

$$\sigma = \sigma_y + k_1 (\bar{\epsilon})^n \quad (2)$$

where k_1 is the flow stress increase at $\bar{\epsilon}=1$ and n is the work hardening coefficient ($\partial \ln \sigma / \partial \ln \bar{\epsilon}$), which for most metals takes values between 0.05 and 0.5.

If the initial yield stress is low compared with the work hardening, the above relation can be reduced to the Hollomon law:

$$\sigma = k_2 (\bar{\epsilon})^n \quad (3)$$

These power laws apply reasonably well to the para-bolical part of the stress-strain curve, typically for strains ≤ 0.5 . At higher strains, the hardening rate decreases so that the flow stress tends to vary nearly linearly with the strain. Two or more pairs of (k, n) values are then required to describe the stress-strain curve over a wide range of deformations. Alternatively, and preferably for large strains, one can use the fact that the flow stress tends to saturate at a value denoted σ_s . In this case, the constitutive law can be approximately described by an exponential relation initially proposed by Voce:^[7]

$$\sigma = \sigma_s - (\sigma_s - \sigma_y) \exp(-\alpha \bar{\epsilon}) \quad (4)$$

Fig. 8 Typical stress-strain curves of Al-Mg alloys^[6]

where α is a dimensionless constant characteristic of the work hardening behavior. In fact, as can be seen in Fig. 9, the saturation stress of aluminum alloys deformed at room temperature is not defined with any great accuracy. Other variants of the Voce law have therefore been proposed of which the most usual, initially due to Hockett and Sherby,^[9] is:

$$\sigma = \sigma_s - (\sigma_s - \sigma_y) \exp(-\alpha \bar{\epsilon}) \quad (5)$$

where the exponent p takes values ~ 0.5 (see Lloyd and Kenny^[6,10]).

Deriving the Voce law gives the current work hardening rate $\bar{\theta}$ as a linear function of the flow stress:

$$\bar{\theta} = \frac{d\sigma}{d\bar{\epsilon}} = \bar{\theta}_0 \left(1 - \frac{\sigma_0}{\sigma_s} \right) \quad (6)$$

where $\bar{\theta}_0$ is the initial work hardening rate. The experimental values of this law are identified by plotting the work hardening rate $\bar{\theta}$ as a function of the flow stress σ . Both parameters are often normalized by the shear modulus μ [i.e., $\theta/\mu = f(\sigma/\mu)$]. Figure 10 illustrates this type of plot at different temperatures ($< 0.4T_m$). Clearly, the work hardening rate, at a given flow stress, decreases with temperature. In addition, it is apparent that at high stresses (and therefore large strains), the work hardening rate does not go to zero; there is a roughly constant residual $\theta \approx 10^{-4} \mu$, independent of temperature.

Microscopical Mechanisms The plastic flow of crystalline materials takes place by the movement of dislocations along crystal planes under the influence of an applied stress. Work hardening is a consequence of the fact that the stress required for dislocation movement usually increases during plastic flow as the dislocations become increasingly hindered by microstructural obstacles. Of the order of increasing size, these obstacles are solute atoms, dislocations, precipitates, and grain boundaries. The most

Fig. 9 Torsion stress-strain curves of several aluminum alloys^[8]

Fig. 10 Schematic of work hardening stages and rates as a function of flow stress at three temperatures

important variation in obstacle density is due to the dislocations themselves.

Dislocations slip in crystallographical directions on planes of easy glide under the influence of a critical applied shear stress τ_c . The emergence of each dislocation creates a displacement along the slip direction of quantity b (the magnitude of the Burgers vector). The amount of shear strain due to the emergence of length l of dislocation in a small volume element is $d\gamma = \rho bl$, where ρ is the dislocation density (in m/m^3 or m^{-2}). In terms of the shear strain rate, this is written $\dot{\gamma} = \rho bv$, where v is the average speed of the mobile dislocations. According to the von Mises law, the plastic deformation of a crystal requires the operation of as many slip systems as imposed strain rate components (≤ 5), so usually several systems (combinations of slip planes and directions) operate and interact in each grain. The shear stress for plastic flow then evolves with strain because the interaction of a moving dislocation with other dislocations usually constitutes a barrier to further movement. This requires an increase in flow stress for the dislocation to continue moving either by circumventing the barrier, or more often by creating a new segment of dislocation, which is then activated in the vicinity. The flow stress therefore increases with dislocation density and the relation between them is usually written:

$$\tau_c = \tau_0 + \alpha \mu b \sqrt{\rho} \quad (7)$$

where τ_0 is the glide stress at zero ρ and α is a material constant (0.2–0.5). For aluminum at 20°C, $\mu = 26 \text{ GPa}$, $b = 0.286 \text{ nm}$, and $\alpha \approx 0.3$, so that $\Delta\tau = \tau - \tau_0 \approx 2.23\sqrt{\rho} \text{ Pa}$ (ρ is in m^{-2}). For dislocation densities typical of a softened, recrystallized metal $\rho \approx 10^{10} \text{ m}^{-2}$ and so $\Delta\tau \approx 0.2 \text{ MPa}$, which is negligible. For $\rho \approx 10^{15} \text{ m}^{-2}$, as in heavily cold-worked alloys, $\Delta\tau \approx 70 \text{ MPa}$ which is obviously significant. Note that the applied macroscopical tensile stress would be about three times τ_c (“Cold Deformation” and “Microscopical-Macroscopical Relations” sections) i.e., $\Delta\tau \approx 210 \text{ MPa}$, which is of the order of the difference in flow stress between the annealed (O-temper) and work-hardened (H) states (Table 2).

This elementary order of magnitude analysis of work hardening can be developed further to characterize the evolution of the dislocation density with strain, alloy content, microstructure, and, at high temperatures, with and $\dot{\epsilon}$. The details and the physical laws can be complicated (and controversial) but the essential features are schematized in Fig. 10 in terms of four stages,^[11] as follows:

Stage I: The dislocations are mostly confined to their slip planes and the interactions occur principally between the dislocation pileups and the grain boundaries. The resistance of the grain boundaries to dislocation movement gives rise to the well-known Hall-Petch grain size (d) hardening relation:

$$\sigma(d) = \sigma_\infty + \frac{k_2}{\sqrt{d}} \quad (8)$$

where σ_∞ is the flow stress of the material at a very large grain size. In the latter case, the dislocations can, initially, move freely with little interaction and the flow stress remains low, but in the general case of polycrystals, Stage I is very short and often neglected, except for the above Hall-Petch relation.

Stage II: The dislocation interactions on different slip systems give rise to a rapid multiplication of the dislocations and the development of dislocation tangles, which often adopt a cellular pattern. This Stage II, which extends up to strains of 0.05–0.2 (or even more at low temperature), is associated with a high work hardening rate $\sim 30 \times 10^4$ to $50 \times 10^{-4} \mu$.

Stage III: Subsequently and up to strains of about unity, the work hardening rate tends to decrease progressively to values of $\sim 1 \times 10^4$ in as the dislocation multiplication processes are counterbalanced by local annihilations (dynamic recovery due to localized climb and/or annihilation of segments of opposite sign). The microstructure evolves toward a well-defined cell substructure (Fig. 11) composed of dislocation cell walls, which delimit cell interiors of low dislocation density. The cells have dimensions that decrease during deformation, typically from a few microns to some tenths of microns. Simultaneously, the misorientation between adjacent cells increases from about 1–3° to 5° (and often higher for heterogeneous deformations).

Stage IV: At higher strains ≥ 1 typical of many rolling and extrusion processes, many grains break up into bands of different orientations, separated by transition zones and grain boundaries (whose total surface per unit volume increases significantly by large plastic deformations). This is characteristic of fibrous micro-structures. As noted above, the work hardening rate in Stage IV, although low, does not go to zero but retains a near-constant value of $\sim 10 \times 10^4 \mu$.

The crystal defects, particularly the dislocations, generated by plastic deformation possess high elastic energies, which are stored in the deformed material essentially in the stress fields around the dislocations. The energy per unit length of dislocation is:

$$E_l = \frac{\mu b^2}{K} \cdot \ln \left(\frac{R}{R_0} \right) \quad (9)$$

(with $K=4\pi$ for screws, or $4\pi(1-\nu)$ for edge-type dislocations). R is the outer cutoff radius of the dislocation stress field ($\approx$ the distance between dislocations, or $\rho^{-1/2}$) and R_0 is the core radius ($\approx 2b$). For typical densities of 10^{-14} to 10^{-15} m^{-2} , $E_l \approx 0.5\mu b^2$ and the stored energy/unit volume $E_v \approx -0.5\rho\mu b^2$. This value varies from 50 kJ/m^3 for lightly deformed aluminum to $2 \times 10^4 \text{ kJ/m}^3$ for heavily deformed steel.

Influence of Alloying Elements The strong influence of alloying elements on work hardening behavior is related to the metallurgical state of the material and depends particularly on whether the elements are in solid solution, or in a dispersion of second-phase particles.

In solid solutions, certain elements such as Mg and Cu segregate to the dislocation cores and significantly reduce their mobility. This tends to confine the dislocations to slip planes, reduce their capacity to recover dynamically by local climb and cross slip, inhibit the formation of “clean” cell structures, and thereby increase the dislocation

density for a given deformation. In general, Stage II work hardening is prolonged and Stages III and IV are retarded so the alloy work hardens extensively (see the example of Al-Mg; Fig. 8). At moderate temperatures (between room temperature and $\sim 300^\circ\text{C}$), the reduced dislocation mobility by solute segregation tends to favor heterogeneous deformation by Lüders bands and Portevin LeChatelier serrations in the stress-strain curves^[12] (Fig. 12).

Elements in the form of second-phase particles usually harden the material by requiring the dislocations to expend additional energy by either cutting the particle (fine particles of radius $r_p \leq 10$ or 20 nm), or by looping around them ($r_p \geq 20 \text{ nm}$). The effect of these processes on the yield strength is well documented because they control, in part, the final properties (Fig. 13).

The effect of second-phase particles on work hardening (i.e., after yield) depends critically on the particle size but in a rather different way. The work hardening rate tends to be rather low for very fine particles (including the peak hardness distributions) because the dislocations, once they have cut through one particle, can cut through entire fields of particles at roughly the same stress. This leads to the formation of shear bands in which plastic deformation is heavily concentrated (e.g., certain Al-Cu alloys). On the

Fig. 12 Stress-strain curves showing serrated flow and the PLC effect in Al-2% Mg^[12]

Fig. 11 Substructure of aluminum alloy deformed at room temperature (Al-1.3% Mn)^[48] (a) Microband structure (as-deformed); (b) subgrain structure (after recovery)

Fig. 13 The influence of particle size on yield strength

other hand, if the particles have dimensions $\geq 1 \mu\text{m}$, the dislocations loop around them and, on continued straining, build up high local dislocation densities near the particles and therefore relatively high work hardening rates. In fact, a considerable fraction of the dislocation population is required to accommodate the difference in plastic strain between the hard particles and the soft matrix; they are termed geometrically necessary dislocations (GNBs).^[13] The accumulation of dislocations in these particle deformation zones creates high local stresses if the particles are sufficiently large to withstand them ($\geq 1 \mu\text{m}$). This process creates a strongly dislocated substructure with a dimension characteristic of the interparticle distance and is particularly pronounced if the particles are nonspherical [e.g., discs (Al-Cu) or fibers].

Microscopical Hardening Laws The macroscopical hardening laws of “Cold Deformation” and “Macroscopical Laws” sections) are essentially empirical descriptions of some parts of the flow curves; they are incapable of describing a complete through-process material behavior during rolling schedules. It is now recognized that microscopical-based models of work hardening using internal variables such as the dislocation density are required for an accurate modeling of plastic flow. The particular microscopical laws are often complex so the relatively simple analysis given below in terms of the total dislocation density can be considered as an illustration of the principles.

The microscopical work hardening rate $d\tau_c/d\gamma$ can be written in terms of the variation of the dislocation density as:

$$\frac{d\tau}{d\gamma} = \frac{d\tau}{d\rho} \cdot \frac{d\rho}{d\gamma} \quad (10)$$

Using the standard $\tau_c(?)$ relation (Eq. 7), the variation of the critical shear stress with dislocation density is:

$$\frac{d\tau}{d\rho} = \frac{\alpha\mu b}{2\sqrt{\rho}} \quad (11)$$

According to the analysis of Kocks^[14] and Mecking,^[15] the rate of creation of dislocations ($d\rho^+$) during a small strain increment $d\gamma$ is inversely proportional to the mean dislocation slip distance λ so that $d\rho^+/d\gamma = l/b\lambda$ and the mean slip distance $\lambda = C_1/\sqrt{\rho}$, where C_1 is the average number of obstacles that the dislocation meets before stopping:

$$\frac{d\rho^+}{d\gamma} = \frac{\sqrt{\rho}}{C_1 b} \quad (12)$$

It can be noted that this relation between the rate of creation of dislocations and $\sqrt{\rho}$ is not accepted by all authors, some

of whom (e.g., Laasraoui and Jonas^[16]) prefer a constant value.

During Stage II hardening, where dislocation annihilation is small and can be neglected, the above model gives a constant hardening rate:

$$\frac{d\tau^{\text{II}}}{d\gamma} = \frac{\alpha\mu b}{2\sqrt{\rho}} \cdot \frac{\sqrt{\rho}}{C_1 b} = \frac{\alpha\mu}{2C_1} \quad (13)$$

If the experimental value of this rate is $5 \times 10^{-3} \mu$, C_1 is about $50 \mu\text{m}^{-1}$, and assuming that $\rho \approx 10^{14} \text{ m}^{-2}$, the average slip length would be about $5 \mu\text{m}$.

During Stage III, the hardening rate decreases continuously as some of the dislocations are annihilated by dynamic recovery at a rate written as $d\rho^-/d\gamma$. The exact mechanisms of annihilation (cross slip, climb) are the subject of current research, but one can write that the rate of annihilation is proportional to the current density ρ and a probability of elimination $P(T)$, which is strongly temperature-dependent:

$$\frac{d\rho^{\text{III}}}{d\gamma} = \frac{d\rho^+}{d\gamma} - \frac{d\rho^-}{d\gamma} = \frac{\sqrt{\rho}}{bC_1} - C_2 P(T) \rho \quad (14)$$

consequently, Stage III work hardening rate becomes linear in τ_c :

$$\frac{d\tau_c^{\text{III}}}{d\gamma} = \frac{\alpha\mu}{2C_1} - \frac{C_2 P(T)}{2} \cdot \tau_c \quad (15)$$

This law can be expressed in the following form for the macroscopical stress: $d\sigma^{\text{III}}/d\varepsilon = \theta_0(1 - \sigma/\sigma_s)$, which is the hardening rate in the Voce law (Eq. 6).

At large strains and at low temperatures, dislocation annihilation is insufficient to completely balance the rate of creation. This results in the low, but nonzero, work hardening rate of Stage IV; there is no general agreement on the basic physical causes of this stage.

Finally, it should be noted that the above analysis assumes only one internal variable, the total dislocation density. Several recent two-parameter or three-parameter models take account of the different dislocation distributions (cell walls, cell interiors, etc.). The added complexity usually enables one to better define transition behavior (varying T , $\dot{\varepsilon}$, etc.).^[17,18]

Microscopical-Macroscopical Relations The plastic flow properties (e.g., the work hardening behavior) of all crystalline solids are described in terms of basic mechanisms by the microscopical quantities (τ_c , $\dot{\gamma}$...) but are usually measured in terms of the macroscopical parameters (σ , $\dot{\varepsilon}$...). The section below briefly describes the relations between them and the way they can be used to understand and to analyze the important properties of textures and anisotropy.

The shear stress on a slip system (defined by its plane normal $\mathbf{n}$ and slip direction $\mathbf{b}$) is related to the macroscopically applied stress σ by the standard relation:

$$\tau^s = b_i^s \sigma_{ij} n_j^s \quad (16)$$

where b_i^s and n_j^s are the direction cosines of the slip direction $\mathbf{b}$ and the slip plane normal $\mathbf{n}$ (with respect to the reference coordinate system). The same geometrical factors enter into the relation linking the components of the strain rate tensor $\dot{\epsilon}$ with the slip rates $\dot{\gamma}$ of the glide systems:

$$\dot{\epsilon}_{ij} = \sum_s \frac{1}{2} (b_i^s n_j^s + b_j^s n_i^s) \dot{\gamma}^s \quad (17)$$

The sum of the slip rates $\sum \dot{\gamma}^s$ in a grain g is used to define the Taylor factor of the grain $M(g)$. This factor relates the microscopical and macroscopical flow properties by the plastic work rate $\dot{W}(g)$:

$$\dot{W}(g) = \sum_s \dot{\gamma}^s \tau_c^s = \sigma(g) \dot{\epsilon}(g) \quad (18)$$

If one assumes that the critical shear stresses of the different slip systems are identical (termed isotropic latent hardening and probably quite reasonable for aluminum), then:

$$M(g) = \frac{\dot{W}(g)}{\tau_c \dot{\epsilon}} = \frac{\sum \dot{\gamma}^s(g)}{\dot{\epsilon}} = \frac{\sigma(g)}{\tau_c} \quad (19)$$

For a polycrystalline aggregate, the average Taylor factor over all grains $\langle M \rangle$ can be calculated for a given distribution of orientations. In the case of the tensile deformation of an fcc metal with a random orientation distribution, $\langle M \rangle = 3.06$. However, nonrandom distributions as in textured polycrystals lead to other $\langle M \rangle$ values; typically, they lie in the range 2–4. The Taylor factor is also important for the work hardening behavior. To first order for small strains $\sigma \langle M \rangle \tau_c = \langle M \rangle / d\epsilon$ and therefore $d\sigma/d\epsilon \approx \langle M \rangle (d\tau/d\epsilon)$ so that if $d\epsilon = \sum d\gamma / \langle M \rangle$, then $d\sigma/d\epsilon \approx \langle M \rangle^2 (d\tau / \sum d\gamma)$ (i.e., the microscopical and macroscopical work hardening rates are related by the square of the Taylor factor).

During plastic deformation, the individual grains undergo lattice rotations toward certain orientations, leading to the formation of deformation textures ("Rolling Textures" section). During this process, the grains rotate at rates that are functions of the above geometrical parameters b_i^s and n_j^s . In general, the rotation rate of the crystal lattice during plastic deformation is $\dot{r} = d - \sum_s b_i^s n_j^s \dot{\gamma}^s$, where $\dot{d}$ is the velocity gradient tensor imposed on the material by the deformation process and the second term is the velocity gradient tensor of the grain due to slip on the activated systems.

Hot Deformation Flow Stresses

At homologous temperatures above $0.4T_m$, plastic deformation is strongly influenced by thermally activated processes so that the flow stress becomes temperature-dependent and strain rate-dependent (viscoplastic). The processes involved are mostly controlled by local atomic diffusion and give rise to a strong dynamic recovery of the dislocation substructure and reduced flow stresses. The latter tend to saturate at a value function of T , $\dot{\epsilon}$, and alloy content. It is generally recognized that the T and $\dot{\epsilon}$ terms can be regrouped into a temperature-corrected strain rate known as the Zener-Hollomon parameter $Z = \dot{\epsilon} \exp(Q/RT)$, where R is the gas constant and Q is an apparent activation energy for plastic flow. For many aluminum alloys, $Q \approx 156$ kJ/mol.

At low Z values (typically $\ln Z \leq 26$ for Al), plastic flow is purely viscous after an initial transition strain of about 0.1. At higher Z ($26 \leq \ln Z \leq 50$), the flow stress also depends on the applied strain [i.e., $\sigma = f(T, \dot{\epsilon}, \epsilon)$]. Note that in typical hot rolling schedules, $\ln Z$ varies from about 22 in the first passes to about 33 near the end.

In the low Z regime, many studies have shown that the saturation flow stress σ_s can be related to the Zener-Hollomon parameter by a power law:

$$\sigma_s = A \cdot Z^m \quad (20)$$

where m is the strain rate sensitivity $\partial \ln \sigma / \partial \ln \dot{\epsilon}$, typically 0.1–0.3.

Blum^[19] has shown that the saturation flow stresses of different materials can be correlated by normalizing with respect to the self-diffusion coefficient D and the shear modulus μ (Fig. 14):

Fig. 14 The temperature and strain rate dependence of saturation flow stress for Al-5% Mg.^[19] Note the power law relation at low s (low Z) and the power law departure at higher s (high Z)

$$\left(\frac{\sigma_s}{\mu}\right) = \left(\frac{\dot{\epsilon} k_B T}{D \mu b}\right)^m \quad (22)$$

In the higher Z regime typical of most hot rolling schedules, the relations $(T, \epsilon, \dot{\epsilon})$ are more complex and often represented by an empirical law due to Sellars and Tegart:^[20]

$$Z = A_2 (\sinh \omega \sigma_s)^{n'} \quad (22)$$

where A_2 , ω , and n' are parameters to be evaluated experimentally. At low Z values, this law is similar to the above power law. At high Z , the sinh law can be reasonably well approximated by an exponential function:

$$z \cong A_3 \exp [\beta \sigma(\epsilon)] \quad (23)$$

where $\sigma(\epsilon)$ is the flow stress at a given value of the applied strain and $\beta = \omega n v$.

To describe an entire work hardening curve in this regime, there are two possible approaches: (a) purely empirical, using a variant of the Voce law where the stresses are functions of Z (e.g., the law used recently by Shi et al.^[21]):

$$\sigma = \sigma_e + (\sigma_s - \sigma_e) \left[1 - \exp\left(\frac{-\epsilon}{\epsilon_r}\right) \right]^m \quad (24)$$

where ϵ_r is a transition deformation and $m \sim 0.5$. An example of this type of representation for the stress-strain curves of an Al-1% Mn alloy at different T and $\dot{\epsilon}$ is given in Fig. 15; and (b) modified Kocks-Mecking approach, which allows

for the effect of different microscopical variables on the rates of accumulation and annihilation of the dislocation populations (usually more than one). The reader is referred to Mughrabi,^[17] Nes,^[18] and the reviews of Gil Sevillano^[22] and Argon.^[23]

Hot Deformation Microstructures The hot deformation microstructures of most aluminum alloys are essentially composed of dislocation subgrains within each of which there is a relatively low density of free dislocations. The processes of dynamic recovery (cross-slip, dislocation annihilation by local climb, etc.) limit the accumulation of free dislocations so the flow stress saturates rapidly at a level controlled by the subgrain size (δ) and the dislocation contents of the subgrain walls and interiors. These microstructural parameters depend essentially on the T , $\dot{\epsilon}$, and solute atom dislocation interactions. During plastic flow, the subgrain boundaries (unlike the grain boundaries) are continually annihilated and replaced by new ones by a dynamic polygonization of the free dislocations, so that their average size (δ) remains constant over very large strains. Their average misorientation tends to saturate at strains about unity but may also continue to increase for some alloys and deformation modes.

A frequently used relation between subgrain size and flow stress is of the form:

$$\sigma = \sigma_0 + \frac{k \cdot \mu b}{\delta^c} \quad (25)$$

where the constant $k \sim 8$ and the exponent c is between 0.75 and 1.5 according to the alloy and deformation conditions; to the first order, it is often taken as 1.

Fig. 15 Experimental and calculated plane strain compression stress-strain curves of Al-1% Mn at different temperatures and strain rates^[21]

A more sophisticated version of the above is taken from Nes^[18] and allows for the influence of free dislocations within the cells ρ_i , that is,

$$\sigma = \sigma_0 + \alpha_1 \mu b \sqrt{\rho_i} + \alpha_2 \frac{\mu b}{\delta} \quad (26)$$

Softening by Recovery and Recrystallization

Phenomenology

During deformation, the strength of a metallic material increases substantially, whereas its residual deformability decreases. As described above, this work hardening is caused by the formation and the storage of dislocations on deformation. Although these dislocations are thermodynamically unstable, at room temperature, processes to rebuild the resulting dislocation structure are too slow to enable significant changes. On a subsequent annealing treatment, however, thermally activated processes give rise to a release in dislocation energy accompanied by a decrease in material strength. As a result, the material may be subjected to further deformations. For instance, thin aluminum converter foil is rolled from a 600-mm cast slab down to a 6.5- μm final gauge (see “Aluminum Foil Products for Packaging” section). Such a total strain of as much as 99.999% thickness reduction ($\epsilon > 10$) can only be achieved with the help of repeated softening processes that occur along the entire thermomechanical processing of the foil. As an example, Fig. 16 shows the evolution of Vickers microhardness with annealing time for different annealing temperatures. The hardness curves imply that the softening behavior may roughly be subdivided into three steps, which correspond to the mechanisms of recovery/nucleation, (primary) recrystallization, and grain growth.^[24] Figure 17

schematically summarizes the microstructural processes during these steps.

During the early stages of annealing, the material gradually softens, which is caused by recovery reactions. The term “recovery” combines all reactions leading to changes in the as-deformed microstructure through dislocation reactions, including dislocation, annihilation, and rearrangement of dislocations into more stable cell or subgrain structures (Fig. 17a and b). Under certain circumstances, recovery is so extended that essentially the entire excess dislocation density is removed through recovery (see, for instance, the curve for 350°C in Fig. 16, “Extended Recovery and Continuous Recrystallization” section).

In most cases, by contrast, recovery reactions give rise to the formation of recrystallization nuclei, which, after a certain incubation period, appear at distinct locations in the as-deformed microstructure (Fig. 17c, “Nucleation” section). During further annealing, these nuclei grow by consumption of the deformed matrix until they impinge with other growing grains. These processes lead to a complete transformation of the microstructure, which, originally, gave rise to the term “recrystallization.” The driving force for this so-called primary recrystallization is provided by the reduction in dislocation density. Recrystallization is characterized by the formation of new grain boundaries during nucleation and their subsequent motion into the as-deformed microstructure. Accordingly, recrystallization is accompanied by characteristic texture changes (“Recrystallization Textures” section), which may be used to monitor the progress of recrystallization and to elucidate the underlying recrystallization mechanisms. In terms of the mechanical properties, the progress of recrystallization is manifested by a rapid hardness decrease (Fig. 16).

Following this primary recrystallization, the recrystallized grains may coarsen further. Here, the driving force is

Fig. 16 Evolution of Vickers microhardness H_v with annealing time t as a function of annealing temperature (Al-1.3% Mn, 97% cold-rolled)^[48]

Fig. 17 Schematic diagram of the processes that may occur during the annealing of a deformed metallic material. (a) Deformed grain structure; (b) recovered subgrain structure; (c) partially recrystallized structure; (d) recrystallized structure; (e) continuous grain growth; and (f) discontinuous grain growth^[24]

provided by the reduction in the energy stored in the grain boundaries. Grain growth processes may take place either continuously (Fig. 17e), or discontinuously (secondary recrystallization; Fig. 17f), with the latter being favored in the presence of second-phase particles, or in materials with a pronounced texture. In most cases, grain growth processes stop when the grain size reaches the smallest specimen dimension (e.g., the thickness of a rolled sheet). In some cases, especially in very thin sheets, however, a few grains may continue to grow discontinuously. Depending on the annealing atmosphere, these processes may be accelerated, suppressed, or even reversed. To differentiate this from secondary recrystallization, the latter process—driven by differences in the anisotropy of the specific energy of different crystal surfaces—is labeled tertiary recrystallization.

Driving Force

In contrast to the exact atomistic processes acting on recrystallization, the energetical causes of recrystallization are quite well understood. The driving force for primary recrystallization is provided by the reduction in elastic energy due to the dislocations stored in the as-deformed state. A brief estimate of the driving force p_D yields:

$$p_D = \Gamma \cdot \Delta\rho = \frac{\mu \cdot b^2}{2} (\rho_{\text{def}} - \rho_{\text{RX}}) \approx \frac{\mu \cdot b^2}{2} \cdot \rho_{\text{def}} \quad (27)$$

(where Γ is the line energy and ρ is the density of the dislocations). For heavily deformed aluminum alloys with a dislocation density of as much as $\rho = 10^{16} \text{ m}^{-2}$, this results in a driving force on the order of $10^7 \text{ N/m}^2 = 10 \text{ MPa}$.

As noted above, recovery reactions that take place dynamically during the deformation or statically during the first seconds of a subsequent recrystallization annealing will transform the dislocations into a more or less well-defined cell or subgrain structure (e.g., Refs. [11] and [26]; “Cold Deformation” and “Microscopical Mechanisms” sections). In that case, the driving force p_D is comprised of two contributions, the energy stored in the cell or subgrain boundaries, and the energy of the free dislocations in the cell interior:

$$p_D = \frac{\alpha \gamma_{\text{SB}}}{\delta} + \frac{1}{2} \mu b^2 \cdot \rho_i \quad (28)$$

(where α is the geometrical constant on the order of 3, and γ_{SB} is the specific subgrain boundary energy). The dislocation density within the subgrains ρ_i and the average subgrain size δ have been found to be linked through the relation $\sqrt{\rho_i} = C/\delta$ where C is an alloy-dependent constant on the order of 2. Both the energy of a subgrain or low-angle grain boundary γ_{SB} and the energy of an ordinary high-angle grain boundary γ_{GB} can be expressed in terms of the well-known Read-Shockley relation, so that the driving force p_D can be rewritten as:

$$p_D = \frac{\alpha \gamma_{\text{GB}} \theta}{\delta \theta_c} \ln \left(\frac{e \theta_c}{\theta} \right) + \frac{C^2 \mu b^2}{2 \delta^2} \quad (29)$$

θ and θ_c , respectively, denote the average and the maximum angle between neighboring subgrains. Whereas θ_c is usually estimated to be 15° , θ varies with strain e to values from 3° to 5° .

For typical data of heavily cold-rolled aluminum ($\gamma_{\text{GB}} = 0.25 \text{ J/m}^2$, $\theta = 3^\circ$, and $(\delta = 0.3 \mu\text{m})$, the contribution of the free dislocations is negligible compared with the energy stored in the subgrain boundaries. The driving force becomes $p_D \approx 10^6 \text{ N/m}^2 = 1 \text{ MPa}$, which is about one order of magnitude smaller than the value derived for a homogeneous distribution of dislocations (Eq. 27). In hot-rolled aluminum ($\theta = 5^\circ$ and $\delta = 1.5 \mu\text{m}$), the driving force is even smaller, $p_D = 3 \times 10^5 \text{ N/m}^2 = 0.3 \text{ MPa}$.

The driving force for grain growth processes p_{GG} is provided by the reduction in grain boundary area and, thus, in (absolute) grain boundary energy:

$$P_{\text{GG}} = \frac{2\gamma_{\text{GB}}}{R}; \quad R = 5, \dots, 10d \quad (30)$$

(where R is the curvature of the grain boundary and d is the grain size).

Kinetics

From a technological point of view, recrystallization kinetics is of outmost importance. As an example, Fig. 18 shows the evolution of the recrystallized volume fraction X as a function of the annealing time t for different tensile-strained Al samples.^[27] The data of the evolution of the recrystallized volume fraction with time $X(t)$ can be determined metallographically, or derived from the changes in mechanical properties (Fig. 16). A promising technique to determine recrystallization kinetics is provided by calorimetric measurements of the energies released during recovery and recrystallization,^[28] although

Fig. 18 Recrystallized fraction X as a function of annealing time t in tensile-strained aluminum (annealing temperature 350°C)^[27]

it is difficult to interpret DSC data for aluminum alloys that undergo precipitation reactions.

Primary recrystallization takes place by nucleation and subsequent growth. Thus, for a quantitative description of recrystallization, the thermal dependency of both processes must be taken into account:

$$\dot{N} = \dot{N}_0 \cdot \exp[-Q_N/(kT)]; \quad \dot{\nu} = \dot{\nu}_0 \cdot \exp[-Q_v/(kT)] \quad (31)$$

(where k is the Boltzmann constant and T is the temperature). The nucleation rate $\dot{N}$ is the number of newly formed grains per volume and time in the nonrecrystallized volume $1-X$; $\dot{\nu}$ is the growth velocity of the new grains. Q_N and Q_v are the activation energies of thermally activated nucleation and growth, respectively.

At variance with the classical nucleation processes of solidification and phase transformations, the reduction in dislocation density during recrystallization is an irreversible process whose driving force is essentially independent of temperature (except for the minor temperature dependency of Burgers vector and shear modulus; Eqs. 27 and 29). Nonetheless, the progress of recrystallization is often characterized by a recrystallization temperature T_{RX} , at which recrystallization is completed in a given time, say 1 hr. Because of the thermal activation of both nucleation and growth processes, a minor change in temperature leads to large changes in recrystallization time; in contrast, changes in the prescribed time necessary to complete recrystallization to, say, 0.5 or 2 hr give rise to only marginally changed recrystallization temperatures.

For a quantitative description of the characteristic S-shaped kinetics curves (Fig. 18), the Johnson-Mehl-Avrami-Kolmogorov (JMAK) equation is generally utilized:^[29–31]

$$X(t) = 1 - \exp\left[-\left(\frac{t}{t_{RX}}\right)^q\right] \quad (32)$$

(where q is the so-called Avrami exponent and t_{RX} is the recrystallization time.) The JMAK equations allow one to determine parameters of technological interest, including recrystallization time t_{RX} and recrystallized grain size d_{RX} . Under certain conditions, N and ν can be derived and the progress of recrystallization can be quantified. The assumption of a constant nucleation rate and isotropic growth yields an Avrami exponent of $q=4$, and it follows that:

$$t_{RX} = \sqrt[4]{\frac{3}{\pi \dot{N} \dot{\nu}^3}}; \quad d_{RX} = 2\nu t_{RX} = 2^q \sqrt[4]{\frac{3\nu}{\pi \dot{N}}} \quad (33)$$

If nucleation prevails at the early stages of recrystallization (“site-saturated nucleation”), $q=3$. Experimentally, the Avrami exponent can be determined from a plot of the expression $\ln\{\ln[1/(1-X)]\}$ versus $\ln t$.

Based on the JMAK equation, the kinetics and microstructure evolution accompanying recrystallization can be modeled.^[32–35] Nuclei are assumed to form in a given simulation volume with a certain rate. Textural effects may be incorporated through a distinct spatial or orientational correlation of the nuclei, and/or through orientation-dependent nucleation rates. Then, the nuclei grow in accordance with the JMAK equation until impingement. Again, orientation-dependent growth rates may be considered. The resulting microstructure (grain size and shape) is revealed by two-dimensional sections through the three dimensional simulation space.

Recovery

From Fig. 16, it is evident that during the early stages of annealing, the material gradually softens, which is attributed to recovery reactions. The term “recovery” combines all reactions leading to changes in the as-deformed microstructure through dislocation reactions. Recovery can take place dynamically (i.e., during the deformation) or statically (i.e., after deformation has been completed, typically during a subsequent annealing treatment). Because of the high stacking fault energy and the high homologous temperature of aluminum recovery, reactions are typically quite pronounced. At elevated temperatures, dislocations may cross-slip and, at higher temperatures, may climb so that blocked dislocations are remobilized. Thus, dislocations can annihilate, which reduces the overall dislocation density. Furthermore, the as-deformed substructure characterized by microbands (Fig. 11a) may be rearranged into energetically more stable, lower-energy configurations such as cell structures and, on further recovery, into a well-defined subgrain structure (Fig. 11b). During further annealing, the subgrains coarsen by the reduction in subboundary energy. Subgrain coarsening may occur through the mechanism of subgrain coalescence as originally proposed by Li^[36] and Hu.^[37]

In most cases, however, subgrain coarsening will take place through subgrain boundary motion (i.e., analogous to ordinary grain growth).^[38,39] During this subgrain growth, the misorientations between neighboring subgrains may slightly increase as, for example, recently studied in detail in commercial-purity aluminum by Furu et al.^[40] Despite the obvious microstructural changes during recovery, the textures remain virtually unaffected, except for a slight sharpening of the texture^[41,42].

Extended Recovery and Continuous Recrystallization

In principle, the dislocations brought into the material during deformation can be released solely by recovery. For instance, on deformation of high-purity metals, or in samples deformed at high temperatures, dynamic recovery can reduce the dislocation energy so efficiently that no

recrystallization is initiated.^[43] In Al alloys, this extended recovery is of particular importance when solution-treated alloys are annealed at low temperatures such that precipitation reactions can interfere with the recrystallization process.^[44,45] Under such circumstances, the subgrain boundaries may be pinned by finely dispersed precipitates and, therewith, nucleation of recrystallization is strongly retarded or even completely suppressed (Fig. 19a). Thus, provided the sub-grain boundaries cannot break free from the particles, the substructure evolution is controlled by subgrain growth governed by the coarsening of the particles^[45–47] (Fig. 19b). Under extreme circumstances, especially in highly strained two-phase alloys with large local orientation perturbations, these processes can eventually lead to the formation of high-angle grain boundaries and microstructures that strongly resemble those of materials that have undergone discontinuous recrystallization^[49,50] (Fig. 19c). This gave rise to the terms “continuous recrystallization” or “recrystallization in situ,” although the underlying mechanisms are inherently different from genuine, discontinuous recrystallization, which will now be discussed.

Nucleation

In most cases, during the annealing of a deformed microstructure, genuine recrystallization occurs through the formation of recrystallization nuclei at some distinct places in the microstructure followed by their growth under consumption of the as-deformed neighborhood. According to classical nucleation theory, supercritical nuclei that will be able to grow form through thermal fluctuations. At critical sizes, the reduction in volume free enthalpy $\Delta g_v \cdot dV$ associated with the formation of a nucleus of volume V just

balances the energy increase associated with the creation of a new grain boundary of area A . Thus, for the critical nucleus size r_{crit} , it holds:

$$r_{\text{crit}} = \frac{2\gamma_{\text{GB}}}{P_D} \quad (34)$$

This estimate yields a critical nucleus size on the order of 0.1, ..., 0.5 μm and, correspondingly, a critical nucleation energy on the order of $\Delta G_c \approx 2 \times 10^{-13} \text{ J/mol} \approx 10^6 \text{ eV}$. This results in a nucleation probability on the order of $N/N_0 \approx \exp(-10^7)$, which is so small that thermal nucleation of recrystallization can completely be ruled out.

The above argument clearly proves that the “recrystallization nuclei” cannot form by thermal fluctuations, but must be provided by other means. In materials with a high stacking fault energy such as aluminum, the formation of new orientations by recrystallization twinning does not play an important role, so that the orientations of the recrystallization nuclei must already preexist in the deformed microstructure (preformed nuclei; e.g., Refs. [51–53]). Nonetheless, because of the strong analogies between the microstructural processes acting during recrystallization and nucleation and growth during thermodynamic phase transformations, the same terms are commonly used to describe recrystallization.

Considering the substructure of (recovered) deformed aluminum and the critical nucleus size on the order of a few tenths of a micron (Eq. 34), this implies that, in principle, all dislocation cells or subgrains may be regarded as potential nuclei. This, however, raises the question of why so few subgrains actually act as nuclei. For an average subgrain size of 1 μm after recovery and a typical final grain size of 50 μm , only one out of 125,000 subgrains becomes a recrystallized grain.

Fig. 19 Extended recovery as caused by the coarsening of finely dispersed second-phase particles. (a) Heavily pinned subgrain structure in cold-rolled, supersaturated Al-1.3% Mn (annealed for $\sim 10^6$ sec at 350°C ; see Fig. 16).^[48] (b) Schematic sketch of subgrain growth controlled by particle coarsening.^[2] (c) Microstructure after continuous recrystallization in Al-1.8% Fe-1.1% Si (96% cold-rolled, annealed for 10^4 sec at 300°C).^[50]

The reason for this extremely low proportion of successful nuclei is attributed to the necessity that the boundary between a nucleus and the surrounding matrix must principally be able to move (i.e., the nucleus must possess a high-angle grain boundary). This implies that during the nucleation period, local misorientations in excess of about 15° have to be formed, whereas recovery in the deformed matrix only provides misorientations that scarcely exceed 10° .^[40] Consequently, nucleation is generally restricted to sites in the vicinity of deformation inhomogeneities, where substantially larger local misorientations are built up already during the preceding deformation.

The requirements of steep orientation gradients with high local misorientations and, therewith, sufficiently high grain boundary mobility are naturally given at the preexisting grain boundaries between the deformed grains. Recrystallization nuclei may form by bulging of a given grain boundary into a grain with a lower dislocation density (strain-induced boundary migration, or SIBM). In Al alloys, which usually comprise a recovered subgrain structure prior to the onset of recrystallization (e.g., Fig. 11b), nucleation at a grain boundary can proceed by the growth of a given subgrain on one side of the boundary into the deformed structure on the other side of the boundary (Fig. 20a). Accordingly, the resulting recrystallized grains will have orientations of the former deformation texture,^[54] including the characteristic R-orientation.^[55] Furthermore, in regions close to the grain boundaries, generally higher dislocation densities and stronger orientation gradients exist due to the activation of additional slip systems to reduce strain incompatibilities at the grain boundaries during deformation. Therefore, favorable conditions for recovery and, consequently, for successful nucleation events prevail in regions close to the grain boundaries (Fig. 20b).

Fig. 20 Nucleation of recrystallization at a preexisting grain boundary. (a) Nucleation through strain-induced boundary migration; (b) nucleation at a grain boundary in a subgrain structure; and (c) example of nucleation at a grain boundary in commercial purity aluminum AA1145 (86% rolled, annealed for 1000 sec at 250°C , scanning electron microscopy)

Similarly, the disturbed zones close to large particles can act as nucleation sites. According to Humphreys,^[56] these so called deformation zones are caused by the deformation incompatibilities at the matrix/particle interface, where very high dislocation densities and, consequently, strong lattice rotations are being built up during rolling. During recovery, the dislocations recover rapidly into subgrains that are substantially smaller than the subgrains in the matrix well away from the particles. In the next stages of annealing, subgrain growth takes place in this very fine local subgrain structure, until finally one or a few large subgrains have consumed the deformation zone and have formed high-angle grain boundaries to the surroundings (Fig. 21). Finally, if their size exceeds the critical diameter of $\sim 1\ \mu\text{m}$, some of the enlarged subgrains may be able to start growing into the deformed matrix. The textures of samples where recrystallization is dominated by this so-called particle-stimulated nucleation (PSN) are typically quite weak with a high fraction of randomly oriented grains. It is worth mentioning here that the formation of the deformation zones depends on the strain rate and particularly on the deformation temperature. At high deformation temperatures and/or low strain rates, dynamic recovery counteracts the formation of the deformation zones and, hence, prevents the occurrence of PSN, as discussed in detail elsewhere.^[57]

Furthermore, other deformation heterogeneities, including transition bands and shear bands, may provide recrystallization nuclei. Because of the highly localized strain,

Fig. 21 Example of PSN in two-phase Al-1.3% Mn containing large Al_6Mn precipitates (80% rolled, annealed for 30 sec at 350°C , transmission electron microscopy or TEM)

they comprise an elevated dislocation density, which, during recovery, leads to rapid subgrain growth and, accordingly, to favorable nucleation conditions. When the critical nucleus size is exceeded, the growth of the nuclei can readily take place due to the high local lattice rotations.

Shear bands are characteristic bandlike deformation heterogeneities that typically form at an angle of approximately 35° to the RD in several Al alloys (Fig. 22) (e.g., in the presence of fine shearable particles,^[58,59] or in alloys with a high concentration of Mg atoms^[60,61]). Transition bands form when an unstable crystal orientation tends to split off into two different orientations on deformation. In Al alloys, cube-oriented grains are often assumed to nucleate in transition bands, which form through a mechanism originally proposed by Dillamore and Katoh.^[62] By Taylor-type model calculations (see “Cold Deformation” and “Microscopical-Macrosopical Relations” sections), it can be shown that during plane strain deformation, all orientations close to the cube orientation in the starting texture rotate about the RD toward the rolling texture orientations. This rotation is divergent, which means that a grain with an orientation along the cube RD rotation path can split during rolling and that the two parts of the grain rotate apart toward two symmetrically equivalent rolling texture orientations. These rotation paths are shown schematically in Fig. 23. The transition band then represents the bandlike remaining part of the splitting grain that still comprises its original orientation.

Growth Processes

The critical size of a recrystallization nucleus in heavily deformed aluminum is on the order of $0.5\text{--}1\ \mu\text{m}$ (“Nucleation” section), whereas typical recrystallized structures reveal grain sizes of $10\text{--}50\ \mu\text{m}$. This size difference underlines the importance of growth effects after the nucleation stage on microstructure and texture of

recrystallized materials. Growth takes place through the movement of grain boundaries into the as-deformed microstructure. Hence, growth is controlled by the mobility of the grain boundaries involved, which, in turn, depends on the structure of the grain boundary plus external factors such as annealing temperature, driving force, and alloy composition, including impurities, etc.^[63–66]

Thermally activated grain boundary motion takes place through the transfer of a given atom from the lattice of the shrinking grain, through the boundary and onto the lattice of the growing grain (Fig. 24a).^[67–69] When a grain boundary moves under a driving force p_D , this elementary step is associated with an energy gain of $p_D b^3$ (b^3 is the atomic volume) (Fig. 24b). The grain boundary velocity v is given by the difference in thermally activated diffusion jumps Γ_i between the two grains:

$$v = \Delta x \cdot (\Gamma_1 - \Gamma_2) = b v_0 c_v^{GB} \left[\exp \left(\frac{-\Delta G}{kT} \right) - \exp \left(-\frac{\Delta G + p_D b^3}{kT} \right) \right] \quad (35)$$

(v_0 is the Debye frequency, $\sim 10\text{ sec}^{-1}$; $\Delta x \approx b$ is the jump distance; ΔG is the activation enthalpy for the diffusion jump; and c_v^{GB} is the vacancy concentration in the boundary). For all recrystallization processes $p_D \ll b^3 kT$, so that:

$$v = b^4 v_0 c_v^{GB} \frac{1}{kT} \exp \left(\frac{-\Delta G}{kT} \right) \cdot p_D = m \cdot p_D \quad (36)$$

Thus, the grain boundary velocity v is proportional to the driving force p_D ; the proportionality factor is denoted by mobility m . It also follows from Eq. 36 that the mobility reveals an Arrhenius-type temperature dependency $m = m_0 \cdot \exp(-Q/kT)$. For an accurate analysis of grain boundary mobility, dedicated experiments with specially prepared bicrystals are best suited. Such experiments have given good evidence of the proportionality between grain boundary velocity and driving force, which, in turn, enables one to derive the mobility as a function of temperature, alloy composition, mis-orientation, etc.^[70]

Fig. 24 On grain boundary motion during the growth of recrystallization nuclei. (a) Schematic sketch of the grain boundary structure; and (b) evolution of the free enthalpy G across a grain boundary under a driving force p_D

Besides temperature, the grain boundary mobility also depends on the misorientation between the two grains. In general, low-angle grain boundaries as well as (coherent) twin boundaries display very low mobility. In contrast, the so-called “special” grain boundaries may have higher mobility than average (i.e., “random” boundaries). This behavior is commonly explained in terms of the so-called “coincidence site lattice” (CSL) theory. The CSL boundaries are thought to be densely packed such that they will absorb less solutes that lower the mobility of random boundaries (see below). However, the grain boundary mobility not only depends on the misorientation, but may also depend on the exact position of the grain boundary plane. Figure 25 reproduces the well-known results of Liebmann et al. on the grain boundary velocity as a function of the misorientation angle for tilt boundaries in aluminum.^[71] Evidently, grains with a 40° orientation relation depict maximum mobility, which will become

Fig. 25 Grain boundary velocity as a function of the misorientation angle for $\langle 111 \rangle$ tilt grain boundaries in aluminum^[71]

important with a view to the interpretation of recrystallization textures where this special orientation relationship is of great importance.

Alloying elements, both in solid solution and in the form of precipitates, may strongly retard recrystallization by exerting a retarding force on the moving grain boundaries. Most works on the influence of solutes on grain boundary motion are based on a model developed simultaneously by Cahn^[72] and Lücke and Stüwe.^[73] This Cahn-Lücke-Stüwe theory is based on the idea that, due to local lattice distortions, solutes close to the grain boundaries have a lower energy than in the undistorted matrix in the grain interior. This difference in energy results in an attractive force dU/dx between the grain boundary and the solute (Fig. 26a) and, therefore, an increased concentration of solutes in the vicinity of the grain boundaries:

$$c_{GB} = C_0 \cdot \exp \frac{U(x)}{kT} \quad (37)$$

(where C_0 is the average solute concentration and c_{GB} is the concentration of solutes in the vicinity of the grain boundary).

If the grain boundary moves, the solutes have to follow the grain boundary by diffusion processes so as to retain their low-energy position (Fig. 26a, dashed line). This results in a retarding force p_F that reduces the driving force and, hence, the grain boundary velocity (“impurity drag”):

$$v = m \cdot (p_D - p_F) \quad (38)$$

At low velocity, the grain boundaries are “loaded” with solutes and the impurity drag increases with grain boundary velocity. At high velocity, the grain boundaries will break away from the solutes and then move more or less freely. In the intermediate regime, there is transition between the behavior of loaded and free boundaries, where grain boundary velocity and driving force may be nonproportional (Fig. 26b).

Fig. 26 Solute drag. (a) Development of potential U , interaction force p , and concentration of solutes c along distance x across a grain boundary. The dashed line indicates the changes in the concentration profile $c(x)$ for a grain boundary that moves from right to left; and (b) grain boundary velocity v as a function of the driving force p for different concentrations of solutes c

Second-phase particles likewise exert a drag on the moving grain boundary. This so-called Zener drag^[74] is caused by the interaction of grain boundary and particles so as to reduce grain boundary area (Fig. 27). The resulting retarding force p_z is given by:

$$p_z = \frac{-3\gamma_{GB}f}{2r_p} \quad (39)$$

(where f is the volume fraction and r_p is the radius of the second-phase particles). Thus, the Zener drag is largest in the presence of small, finely dispersed particles.

Textures

The large plastic strains encountered in rolling operations develop directional structures, or textures, which can strongly influence the resulting mechanical (or physico-chemical) properties of the material. The most well-known effect is the plastic anisotropy of sheet products, an example of which is illustrated in Fig. 28;^[75] the properties in the sheet plane [e.g. σ_y , at an angle α to RD ($\alpha \approx 55^\circ$)] are significantly lower than along RD. This type of anisotropy

Fig. 27 Interaction between a particle and a grain boundary moving under a driving force p (Zener drag)

can also strongly influence formability (e.g., the product shape during a deep drawing operation), as can occur for beverage cans ("Production of Can Body Stock for Beverage Cans" section). The deformation textures developed during rolling can, of course, be modified by annealing to generate new recrystallization textures.

Crystallographical textures in polycrystalline aggregates are characterized by the volume fractions of a particular orientation (g) compared with its theoretical value in a perfectly random set of orientations. Formally, they are represented by an orientation distribution function (ODF) defined by the volume fraction of a material (dv/V), which possesses an orientation within a small angular range dg [i.e., $f(g) = (dv/V)/dg$]. In practice, textured metals are usually composed of grains with orientations close to one or more "ideal" texture components and other grains oriented

Fig. 28 Yield stress anisotropy in a high-strength Al-Li alloy^[75]

Table 4 Miller indices and euler angles of the most important orientations of Al and Al alloys after tolling and after recrystallization (approximated)

Component	Miller indices $\{hkl\}\langle uvw \rangle$	Euler angles $(\varphi_1, \Phi, \varphi_2)$
Cu	$\{112\}\langle 111 \rangle$	$90^\circ, 30^\circ, 45^\circ$
S	$\{123\}\langle 634 \rangle$	$59^\circ, 34^\circ, 65^\circ$
Bs	$\{011\}\langle 211 \rangle$	$35^\circ, 45^\circ, 0/90^\circ$
Goss	$\{011\}\langle 100 \rangle$	$0^\circ, 45^\circ, 0^\circ/90^\circ$
Cube	$\{001\}\langle 100 \rangle$	$0^\circ, 0^\circ, 0^\circ/90^\circ$
Cube _{RD}	$(013)\langle 100 \rangle$	$22^\circ, 0^\circ, 0^\circ/90^\circ$
Cube _{ND}	$\{001\}\langle 310 \rangle$	$0^\circ, 22^\circ, 0^\circ/90^\circ$
P	$\{011\}\langle 122 \rangle$	$70^\circ, 45^\circ, 0^\circ$
Q	$\{013\}\langle 231 \rangle$	$45^\circ, 15^\circ, 10^\circ$
R	$\{124\}\langle 211 \rangle$	$53^\circ, 36^\circ, 60^\circ$

at random well away from the latter (often termed random orientations).

An individual orientation can be defined in several ways; the parameters most used by the texture community are the three Euler angles $(\varphi_1, \Phi, \varphi_3)$, which, by three successive rotations, bring the orientation (g) to some common reference orientation. In cubic materials, the latter would be the three $\langle 100 \rangle$ crystallographical axes parallel to the principal axes of the deformation process (i.e., RD, TD and ND in rolling). The metallurgical community often prefers the Miller indices $\{hkl\}\langle uvw \rangle$, giving the crystal planes and directions of the major texture components aligned with the principal straining directions [i.e., $\{hkl\}$ for the sheet plane and $\langle uvw \rangle$ for the rolling direction]. The correspondences of Miller indices and Euler angles for some typical sheet metal orientations are given in Table 4.

For symmetry reasons, the possible ranges of the Euler angles can be restricted to specific values (e.g., $\varphi_1 = 90^\circ$ for

orthotropic symmetry typical of rolled sheet) so that each orientation is defined by its $((\varphi_1, \Phi, \varphi_2))$ coordinates in a well-defined 3D Euler space. For practical visualization, this 3D Euler space is sectioned into 2D sections of constant φ_2 in which the ideal texture components are easily located. The reader is referred to Bunge,^[76] Kocks et al.,^[77] and Randle and Engler^[78] for further details and particularly the diffraction techniques used to determine textures and ODFs.

Rolling Textures

Sheet rolling textures of fcc metals are usually characterized by continuous spreads of orientations along one of two fibers, denoted as the α and β fibers. The β fiber orientations, usually developed in rolled aluminum, include “Cu” $\{112\}\langle 100 \rangle$, “S” $\{123\}\langle 164 \rangle$, and “Bs” $\{011\}\langle 211 \rangle$. The α fiber components extend from the same “Bs” to “Goss” $\{011\}\langle 100 \rangle$, (i.e., possess an $\{011\}$ crystal plane parallel to the sheet plane). Figure 29 gives an example of the $\{111\}$ and $\{100\}$ pole figures of rolled aluminium sheet, and Fig. 30 gives the corresponding ODF sections.

In cold-rolled aluminum sheets, the strongest components at the sheet center are usually the S and Cu components, together with small but significant amounts of Bs and Goss, in this order. However, the rolling conditions, the alloy content, and the initial texture prior to rolling can influence this order. Cold rolling is always very close to plane strain compression, so the deformation textures tend to be very similar if the same deformation mechanism operates. An important case, treated in detail in “Production of Can Body Stock for Beverage Cans” section, is cold rolling of cube textured sheet for beverage can applications; the cube texture gradually decreases in intensity to be replaced by the β fiber components at high strains.

The rolling textures can be modified only if the strain path and/or the deformation mechanisms change.

Fig. 29 (a) $\{111\}$ and (b) $\{200\}$ pole figures of cold-rolled Al (AA5182, 92% rolled)

Fig. 30 The ODF of the pole figures shown in Fig. 29 (92% cold-rolled Al alloy AA5182)

This occurs at room temperature if the usual slip processes are replaced at high strains by pronounced shear banding, as is observed in some particle-strengthened alloys containing fine shearable precipitates (Al–Li and Al–Cu).

In this case, the intense localized shears along the bands tends to strengthen the Bs and Goss components.^[58] Mechanical twinning has a similar effect but is usually not encountered in current aluminum alloys.

During high-temperature rolling, the deformation textures can be significantly different because there are fewer constraints on both the strain path and the slip systems. The strain path varies because the hot rolling of an ingot by reversible rolling and then tandem rolling (“Hot Rolling” section) superimposes significant shear components on the plane strain compression mode; the shears vary from zero at the center to high values near the surface. Also at temperatures $>0.5T_m$, slip in the aluminum is no longer restricted to the $\{111\}$ planes but can occur on the $\{110\}$ and $\{100\}$ planes (and possibly others) (see Maurice and Driver^[79] and Perocheau and Driver^[80]). An example of the texture variation through the thickness of a reversibly rolled AA3103 alloy is represented in Fig. 31 by $\{111\}$ pole figures. Near the center ($L=0.2$), there is a typical hot rolling β fiber texture albeit with a stronger Bs component than usually found after cold rolling. Midway between the center and the surface ($L=0.5$), the texture is quite different and, near the surface ($L=0.9$), tends to a unique $\{001\}\langle 110 \rangle$ shear component. This develops as a consequence of the reversed shear deformation that material elements undergo both within a pass and from pass to pass. On subsequent tandem rolling, the shear is reduced in amplitude

Fig. 31 Examples of texture variations through the thickness of hot-rolled AA3103. (a) Center; and (b) near surface

and rolling is unidirectional. The deformation mode during tandem rolling then transforms the $\{001\}\langle 110 \rangle$ shear component into two symmetrical $\{112\}\langle 111 \rangle$ Cu components, which form part of the usual β fiber texture. The final hot-rolled plate from the tandem mill has, therefore, a β fiber texture in which the Bs component tends to be strongest in the center and the Cu component tends to be stronger near the surface.^[81]

An important point with regard to subsequent recrystallization texture development is the amount of cube texture left in the as-hot-rolled material. During cold rolling, the cube component is unstable so cube grains gradually break up by deformation banding before ultimately (at $\epsilon \geq 2$) rotating to the β fiber (near-S) components. However, even after large strains, some fragments of the cube grains are left over and can become sites for recrystallization nuclei. During hightemperature rolling, many studies have now shown that the cube grains are stable (as a result of the change of slip systems) up to very large strains and therefore survive the entire hot rolling process as elongated “cube bands.”

The evolution of these rolling textures can be modeled quite successfully by the crystal plasticity models described briefly in “Cold Deformation” and “Microscopical-Macroscopical Relations” sections. An example of a cold rolling texture simulation assuming $\{111\}\langle 110 \rangle$ and plane strain compression is given in Fig. 32a. This shows strong S and Cu components with some Bs. Hot rolling textures and their gradients have also been modeled more recently using FE data for the strains along different material flow lines as shown in Fig. 32b and c. At the center, there is a classical β fiber with strong Bs, S, and Cu components, together with some Bs and Goss. Toward the surface, the alternating shears in the breakdown mill lead to a well-developed $\{001\}\langle 110 \rangle$ shear texture and subsequent (virtual) deformation in the tandem, then destroy most of this shear components to reform a β fiber texture.

Recrystallization Textures

The most common recrystallization textures of rolled and annealed aluminum alloys are the cube $\{001\}\langle 110 \rangle$, the R (or retained S) $\{124\}\langle 211 \rangle$, and, under certain circumstances,

Fig. 32 Numerical simulations of texture evolution during the rolling of aluminum alloys. (a) Cold rolling; (b) reversible hot rolling along center line; and (c) reversible hot rolling near the surface^[5]

the P $\{011\}\langle 122 \rangle$ or Q $\{013\}\langle 231 \rangle$ components. Texture evolution during recrystallization is a complex (and often controversial) subject, so the following will attempt to describe the essential features of the problem, at the risk of oversimplification. The textures depend very sensitively on the details of the nucleation and growth mechanisms outlined in “Softening by Recovery and Recrystallization” section (i.e., are functions of the deformation texture, the microstructure, and, particularly, the solute and precipitate distributions, together with the annealing conditions).

In sheets of pure fcc metals such as aluminum, large rolling reductions and high annealing temperatures strongly favor the cube recrystallization texture as a consequence of rapid nucleation of cube grains from the cube fragments and their growth into the adjacent, highly dislocated matrix (cube with $f_{\max} > 20$). Recrystallization after hot rolling can produce even stronger cube textures. However, even small quantities of Fe in solid solution, as occurs in most commercial aluminum alloys, can modify this texture. For example, Hirsch and Lücke^[82] have shown that cold-rolled Al-0.007% Fe, when annealed at 360°C, leads to a R +cube texture, probably due to the influence of the precipitation of Fe on the migrating boundaries. When both Fe and Si are present (as in the commercial 1xxx alloys), they form Al-Fe-Si phases during casting, which act as nucleation

sites for PSN. Subsequent rolling and recrystallization then promote a degree of texture randomization by PSN (Fig. 33). Note that the cube texture still dominates but $f_{\max} \sim 10$ due to PSN randomization. Because most commercial alloys contain typically ~1% (Fe+Si), clearly PSN will be a major factor controlling recrystallization textures, at least after cold rolling. Recrystallization after hot rolling, as pointed out in “Nucleation” section, is less influenced by PSN because the deformation zones around the particles are reduced by dynamic recovery.^[57]

In the more highly alloyed 2xxx, 5xxx, and 1xxx series, which contain either fine shearable precipitates or high Mg contents, shear banding can occur (“Cold Deformation” and “Influence of Alloying Elements” sections). These deformation inhomogeneities are also nucleation sites for recrystallization (“Nucleation” section) and have been extensively studied by Engler.^[83] It appears that shear bands tend to favor the Goss $\{011\}\langle 100 \rangle$ component and, at very high strains, the Q orientation. If the same alloys are deformed without shear banding, then the other mechanisms such as PSN, SIBM, etc., operate.

Clearly, recrystallization texture development is sensitive to the relative rates of nucleation and subsequent growth from a wide variety of sites in the deformed metal (cube bands, PSN, SIBM, and shear bands) and which obviously depend on the deformation microstructure (i.e., the deformation conditions and the alloy). Theoretical prevision of recrystallization texture development is not easy. However, there is a general tendency for the recrystallization texture to be controlled by the first stages of nucleation and growth, often termed microgrowth, of small micron-sized elements out of the deformation structure and which are often related by 30–40° $\langle 111 \rangle$ rotations with respect to their local

Fig. 33 Recrystallization texture evolution in commercial purity aluminum due to the presence of (Fe+Si) particles

environment. It follows that recrystallization textures can sometimes be modeled by simply taking the deformation texture and by imposing $40^\circ \langle 111 \rangle$ rotations to each component of the deformation texture.^[50,84] As shown in Fig. 34, for random nucleation, which is approximately given when PSN prevails, this transformation texture can give quite a reasonable approximation of the recrystallization texture. A somewhat more sophisticated model has been developed by the Trondheim group^[85] for the case of hot deformed alloys (where shear banding does not intervene). The analysis relies on models for the rates of nucleation and the growth of the PSN, SIBM, and cube band sites as a function of the deformation structure and texture. It can also be extended to predict recrystallization grain sizes.

In a more generalized context, it has been demonstrated that the recrystallization textures of most rolled Al sheets can be modeled by the multiplication of a function representing the probability of the nucleation of the new grains with their growth probability function, with the latter being identical to the $40^\circ \langle 111 \rangle$ transformation texture.^[86,87] The probability of nucleation is given by the distribution of potential nucleus orientations that form at the corresponding nucleation sites, which means that it can be determined experimentally.

More recently, Engler and Vatne have combined these two approaches in that the Trondheim model is utilized to determine the contribution of nucleation at the various characteristic nucleation sites acting in rolled Al alloys (cube bands, grain boundaries, and large particles) to the distribution of nucleus orientations. This approach has been successfully applied to simulate the recrystallization textures of a variety of Al alloys with

different microstructural characteristics processed under different processing parameters, viz. strain, strain rate, and deformation temperature.^[88]

Anisotropy

The crystallographical textures developed by rolling deformation and eventually subsequent recrystallization lead to anisotropic mechanical properties. An example is the variation, with direction in the sheet plane, of the yield strength of an Al–Li alloy as illustrated in Fig. 28. A second case concerns the plastic anisotropy during a forming operation such as deep drawing. A circular blank stamped out of a sheet is drawn down by punching through a die into a cup shape, but the resulting “cup” develops irregular wall heights commonly denoted “ears” (Fig. 35). The ears are situated at certain angles to the sheet directions according to the plastic anisotropy, or the texture, of the sheet (see “Production of Can Body Stock for Beverage Cans” section).

Plastic anisotropy of sheet materials is measured experimentally by the contraction ratios of flat tensile samples taken at angles α to the rolling direction. The ratio of the width (plastic) strain ϵ_w to the through-thickness strain ϵ_t is denoted by the Lankford coefficient or the R value:

$$R = \frac{\epsilon_w}{\epsilon_t} \text{ (or } r = \frac{\dot{\epsilon}_w}{\dot{\epsilon}_t} \text{)} \quad (40)$$

In theory, R varies from 0 (no widening) to ∞ (no thickening) and equals 1 for isotropic materials. Note that some authors use the contraction ratio $q = -\dot{\epsilon}_w / \dot{\epsilon}_l$ measured in terms of the strain rates along the sample width and length (i.e., $q = r/1+r$ and varies from 0 to 1).

To characterize the overall resistance to thinning of a sheet, an average of the R values at three alpha angles is usually determined:

$$\bar{R} = \frac{(R_0 + R_{90} + 2R_{45})}{4} \quad (41)$$

and to measure the amplitude of the in-plane anisotropy (related to the ear heights), the difference value is used:

$$\Delta R = \frac{(R_0 + R_{90} - 2R_{45})}{2} \quad (42)$$

An $\bar{R}$ value greater than 1 means that during elongation, the sheet thins less than it contracts and often indicates good formability. Average $\bar{R}$ values greater than 1 are not common in most aluminum alloys. Only in materials that have been produced to include pronounced shear textures have $\bar{R}$ values of about unity been obtained.^[89]

A more general description of plastic anisotropy is contained in the yield surface. In theory, these are five dimensional spaces that describe the current yield stress as a function of any 5D stress direction. In general practice,

Fig. 34 Rolling-to-recrystallization transformation texture obtained by $40^\circ \langle 111 \rangle$ rotations (Al–Fe–Si, 90% cold-rolled; regions with intensity < 1 are dotted)

Fig. 35 (a) Deep drawing of cylindrical cups and (b, c) typical earring profile with ears under 0° and 90° to the rolling direction developed during cupping of a circular aluminum sheet with strong cube texture (AA3104 hot band). (Courtesy of Dr. J.Hirsch, Hydro Aluminium Deutschland GmbH.)

they are measured in the sheet plane by applying different combinations of in-plane loads so that experimental yield surfaces are essentially 2D. An example of the sheet plane yield surface of an aluminum alloy is given in Fig. 36.

Anisotropy is frequently modeled using the crystal plasticity analysis outlined in “Cold Deformation” and

“Microscopical-Macroscopical Relations sections.” For the extreme case of a single crystal, the basic equation is the generalized Schmid criterion for slip on a system under a general stress state $[\sigma]$:

$$\tau_c^s = \tau^s = b_i^s \sigma_{ij} n_j^s \quad (43)$$

Fig. 36 Anisotropic 2D sheet plane yield surface of textured Al from Ref. [90]. The stresses are normalized to the x -direction yield strength. S indicates the normalized level of τ_{xy}

Assuming that the stress normal to the slip plane has no influence, this can be written in terms of the five-component stress deviator $[s]$ and defines a set of hyperplanes in 5D space. Because, according to the above equation, the glide stress cannot exceed the value τ_c^s , the surface made up of the inner set of hyperplanes describes the stress states for plastic flow; this is termed the (lower bound) single crystal yield surface, or yield locus. For a textured polycrystalline aggregate, the condition of plastic flow is determined both by the Schmid criterion and by the requirements of strain compatibility between grains. An upper bound yield locus is given by the Taylor, Bishop, and Hill analysis by calculating, for all possible strain increments, the associated stress states (i.e., the stress corresponding to the maximum plastic work rate of the material). An example of an upper-bound single crystal yield surface is given in Fig. 37.

For a textured polycrystalline aggregate, the stress state for each strain increment is obtained by an averaging procedure over a representative population of grains, usually

Fig. 37 Upper-bound single crystal yield surface, {110}<112> Bs orientation^[90]

based on the orientation distribution function. This then gives the plastic work rate and the average Taylor factor $\langle M \rangle$. The methods are outlined by Hosford^[90] and Kocks et al.^[77] The yield loci of textured polycrystals tend to be intermediate between the single crystal case of Fig. 37 and the (isotropic) von Mises ellipse (see Fig. 36). All yield loci obey the normality rule according to which the strain rate vector, for a particular stress state on the yield surface, is normal to the yield surface at that point. One of the important features of these textured yield loci are the vertices, which, for a single grain, correspond to a discontinuous change in slip systems for a small change in stress state. According to the normality rule, they imply large changes in strain path with two important consequences: (a) the Lankford coefficient can be very dependent on texture and straining conditions; and (b) pronounced discontinuities of the normal to the yield surface often imply plastic instabilities, which can be more or less localized.

PROPERTIES AND SPECIFIC APPLICATIONS

Introduction

Rolled products (i.e., sheets, plates, and foils) constitute almost 50% of all Al alloys used. In North America and Western Europe, the packaging industry consumes the majority of the sheet and foil for making beverage cans, foil containers, and foil wrapping. Sheet is used extensively in buildings for roofing and siding; in transport for airframes, road, and rail vehicles; in marine applications, including offshore platforms; and superstructures and hulls of boats. Although, to date, only relatively little Al is used in the

manufacture of high-volume production automobiles, it is expected that the next decade will see a substantial increase of aluminium sheet used for body panels. Plates are used for airframes, military vehicles and bridges, ship superstructures, cryogenic and chemical vessels, and as tooling plates for the production of plastic products. Foil applications outside packaging include electrical equipment, insulation for buildings, lithographical plate, and foil for heat exchangers.

In this chapter, several typical examples of the use of aluminum-rolled products will be presented in order to illustrate the impact of the various steps during the processing of rolled Al products on the resulting product properties. In the sequence of thickness variations during rolling, the examples start with the use of thick hot-rolled transfer slab for aeronautical applications. Hot bands with thickness of 4–8 mm may be used for undercarriage and wheels in automotive applications. Examples of cold-rolled strip include hard (i.e., unrecrystallized) can stock for beverage cans as well as soft (i.e., recrystallized) clad brazing sheets for heat exchangers. Furthermore, solution-treated sheets of age-hardenable Al alloys for applications in car body-in-white applications will be addressed. Finally, we will discuss the production of Al foil that is used in numerous applications in packaging.

These examples were chosen to cover a wide range of use of Al alloys in applications of technological importance. In each example, we will discuss the main property requirements as well as the important processing parameters that need to be controlled so as to achieve these requirements. It is worth noting that most of the new products have been developed by a combination of engineering ingenuity and improved scientific knowledge of the physical mechanisms.

Use of Thick Al Plate in Aeronautical Applications

The development of modern air traffic was virtually impossible without the use of aluminum. The combination of good corrosion resistance, high formability, and high strength, and, in particular, the low specific weight, makes Al the most versatile material for aircraft applications. For instance, the Boeing 747 “jumbo jet” contains 75,000 kg of aluminum. Despite the development of new composite materials, Al remains the primary aircraft material, comprising about 70% of a modern aircraft’s weight. The alloys used most widely for aircraft applications are the heat-treatable alloys of the Al–Cu system (2xxx series) and, for components requiring higher strength, the Al–Zn–Mg system (7xxx series). For many years, alloys 2024 and 7075 dominated in aircraft applications. By limiting the contents of accompanying elements, especially Fe and Si, and by optimizing the thermomechanical processing, damage-tolerant variants of these alloys have been established.^[91–93]

The fuselage of commercial aircraft consists of a skin with longitudinal stiffeners (stringers) and regularly spaced frames in the circumferential direction. An important design driver is damage tolerance of the structure, associated, for example, with the tensile stresses introduced in the skin by the pressurization cycle. However, other loadings lead to additional requirements, such as stability in the compression of the lower part of the fuselage. Currently, there is a major development toward welded structures as opposed to riveted ones so as to reduce productions costs.

Wings of commercial aircraft consist of upper and lower wing covers reinforced with riveted or integrally machined longitudinal stringers. Longitudinal spars and transverse ribs are used to stiffen the wing box. Auxiliary structures include leading and trailing edges, control surfaces (ailerons, flaps, slats, etc.), and engine beams. Upper wing components are compression-dominated structures, whereas bottom wing structures are designed for damage tolerance requirements. Intermediate spar and rib components must achieve the best compromise between the technical needs of the upper and lower wings.

The mechanical structure of the horizontal and vertical stabilizers of commercial aircraft can be compared with the structure of the wings, albeit with smaller dimensions, with the fin box and the tailplane outerbox, and the center box and auxiliary structures (leading and trailing edges, elevator, etc.). Loads on the horizontal stabilizers are typically inverted compared with those on a wing, with the need of compression-resistant solutions for the lower parts and damage-tolerant alloys for the upper structures. As far as the vertical stabilizers are concerned, complex loads involving overall bending and local gust loads may occur.

Sheets are typically used in an aircraft for fuselage panels, skins of auxiliary structures (leading/trailing edges), and control surfaces, as well as for bent stiffeners or frames. Tempers vary from annealed “O” to quenched “T” or as-fabricated “F,” depending on the forming operation of the component and the alloy formability. In addition, for outside panels, corrosion protection through cladding with commercial purity Al is often required.

Plates are increasingly used in the structure of commercial aircraft to substitute for assemblies of sheet or small gauge plate and stiffeners by so-called integral or monolithic structures. A conventional assembly usually consists of a number of formed sheets and extruded, forged, and or machined parts, which are riveted together or joined otherwise. An integral structure, on the other hand, integrates the function of all these individual parts into one large structure with the advantage of weight reduction and production cost savings due to the lower number of components. Manufacturing of the integrated structure itself is cost-efficient due to high-speed milling machines, with up to 25,000rpm and high feed rates, which are available today for machining of high-strength Al alloys.

The major challenge for the material suppliers in view of this substitution process is that the property combination

of the raw material should not limit the performance of the integral structure when compared with a classical assembly. For that reason, a number of limitations of conventional Al plates had to be overcome. The maximum thickness of conventional Al plates had to be increased in order to allow the machining of very heavy sections. The residual stress level of the plate material had to be controlled to an extremely low level to guarantee distortion-free machinability even with the large dimensions and the high aspect ratios involved. Residual stresses are relieved by a controlled stretching operation wherein the plates are stretched by a few percent in their long dimension. The development of new alloys with lower quench sensitivity such as 7010 and 7050 led to improved through-hardening properties of thick plates. Additionally, several key properties of the plate material such as corrosion and fatigue resistance, toughness, and ductility had to be improved in order to compete with properties of other product forms.

In general, the fracture toughness of 7xxx series alloys depends on yield stress, chemistry, and on the distribution of second-phase particles.^[94–98] Furthermore, to improve toughness and resistance against stress corrosion cracking, it is necessary to suppress recrystallization. Figure 38 shows the microstructure of alloy 7010 after laboratory deformation through plane strain compression tests,^[42] displaying a fine recovered subgrain structure plus a few strongly enlarged recrystallized grains. In order to suppress recrystallization, elements such as Cr and/or Zr are usually added. In addition, the thermomechanical processing must be controlled so as to minimize postdynamic recrystallization.

Thus, the optimization of the chemical composition, together with an appropriate thermomechanical processing, led to the development of aircraft alloys that combine high strength, high corrosion resistance, and high fracture toughness. These alloys are used in the most recent generation of airplanes such as the Boeing 777, or the planned new Airbus A380 (Fig. 39).

Hot Band for Welded Aluminum Wheels

Light metal wheels made from Al alloys have acquired a large market. However, such Al wheels, which are produced

Fig. 38 Optical micrograph of hot deformed, partially recrystallized AA7010 (etched in chromium acid)

Fig. 39 Airbus A380 (computer simulation; courtesy of EADS)

by casting or forging, are used mainly because of their attractive styling, but with weights of up to 10 kg, they do not offer a large potential for saving weight compared with conventional steel wheels. Therefore, there is an increasing interest in welded wheels made of aluminum hot band.^[99] The deep-drawn disk is joined to the welded rim by MIG welding. With a weight of 5.6 kg, these wheels are about 30% lighter than their steel counterparts (Fig. 40). Thus, although Al wheels are more expensive than steel wheels, they offer the potential of reducing unsprung mass of the chassis, resulting in better ground contact and, there-with, improved safety, handling, and driving comfort, as well as improved fuel efficiency.

For such applications, and for other components of the chassis, naturally hard alloys of the Al–Mg–Mn system (5xxx series) are well suitable.^[100] In the soft state, 5xxx

Fig. 40 Light metal wheel made from 8.6-mm-thick hot band of alloy AA5454. (Courtesy of Hydro Aluminium Deutschland GmbH.)

series alloys exhibit very good formability as required for producing the deep-drawn disks. The strength of Al–Mg alloys strongly increases with strain (Fig. 8), with the entire strength level depending on the Mg concentration. The corrosion behavior of Al–Mg alloys is generally excellent, such that many automotive parts may be used without a protective layer. However, alloys with Mg contents in excess of 3% may suffer from intergranular corrosion when they are exposed for a long time to temperatures in the range 60–200°C. Figure 41 shows the influence of Mg concentration on strength and on the resistance against intergranular corrosion, the latter being expressed as weight changes during annealing for 17 hr at 130°C (ASTM G67). Thus, 5xxx alloys with 2–3% Mg—including the alloys AA5049 (EN AW–AlMg2Mn 0.8), AA5454 (AlMg3Mn), and AA5918 (AlMg3.5Mn)—offer a good compromise between strength and resistance against intergranular corrosion. Age-hardenable 6xxx alloys would allow for further

Fig. 41 Yield strength $R_{p0.2}$ and resistance against intergranular corrosion of 5xxx series Al–Mg alloys as a function of the Mg content. (Courtesy of Dr. D. Wieser, Hydro Aluminium Deutschland GmbH.)

Production of Can Body Stock for Beverage Cans

One of the probably best-known examples of products from rolled Al sheet is the aluminum beverage can, recognized as one of the most innovative packaging containers in the world. In 1999, more than 112 billion aluminum beverage cans were produced in North America (i.e., about 300 cans per person). As illustrated in Fig. 43, the production of the standard two-piece beverage can is carried out in a sequence of drawing and ironing operations. In a press operation, 12–14 circular blanks are stamped out in parallel from highly cold-rolled sheet with thickness of 0.25–0.30 mm, followed by deep drawing into a cup. In a second operation, the “bodymaker,” the cup walls are further ironed down to about 0.1 mm thickness with concurrent forming of the can base. The can top is then trimmed to length. After chemical cleaning, the cans are given their final design by a sequence of internal and external coatings and printing operations. Finally, the cans are necked-in at the top to reduce can diameter and flanged so that the top of the can (Fig. 43) can be attached and sealed after filling. The can end is produced separately in a sequence

Fig. 42 Correlation between the r -value and the deviation in rotational symmetry in a deep-drawn wheel disk. (Courtesy of Dr. J.Hasenclever, Hydro Aluminium Deutschland GmbH.)

of high-speed stamping and forming operations, with up to 28 blanks stamped out in parallel from coil-coated Al. The so-called shells are fed through a high-precision press where rivet making, scoring, and tabbing occur in progressive operations. After the cans and ends are inspected, they are ready for shipping and filling.

The common Al alloys used for the production of can bodies are Al–Mn–Mg alloys of the 3xxx series (AA3004 and AA3104), which meet best the requirements for can strength and formability. Continuous efforts to increase strength for further materials savings by downgauging led to the addition of small amounts of Cu (up to maximum of 0.25%). For the can end, higher strength is achieved through a higher Mg content, ranging from 4% to 5%, as in alloy AA5182. Can tabs used to be produced from an intermediate-strength variant, such as AA5042, but for several years, AA5182 has been used almost exclusively. Typical alloy compositions are listed in Table 5.

The conventional fabrication route for can body sheet consists of DC casting of large ingots, a two-step preannealing (up to 600°C), breakdown hot rolling (at about 500°C) to 20–40 mm transfer slab gauge, followed by tandem hot rolling to about 3-mm hot band with exit (coiling) temperatures of about 300–350°C (“Rolling Schedules” section). Modern multistand hot rolling lines that are optimized for maximum mass output are characterized by a combination of high speed, short interstand times, and large reduction steps, which prevents interstand recrystallization and, accordingly, gives rise to a fairly high-stored energy. Thus, for sufficiently high coiling temperatures, recrystallization will take place in the coiled hot strip, which is referred to as “self-annealing.” The final cold rolling, usually without interannealing, yields a finish gauge sheet with a thickness below 0.3 mm in a high-strength state (condition “H19”).

The major requirements for AA3104 can body stock include sufficiently high strength and good formability. High strength is needed to avoid the buckling of the can base under high internal pressure (dome reversal) and to achieve sufficient structural stability (column strength), which is of particular importance for the very thin can wall thickness below 0.1 mm. The increase in yield strength is achieved by cold rolling. Figure 44 shows the evolution of yield strength $R_{p0.2}$ as a function of (laboratory) cold rolling level, starting from two differently recrystallized hot bands.

Evidently, the properties of the finish gauge sheet are largely controlled by the hot rolling parameters. The hot strip thickness dictates the reduction by cold rolling required to achieve the final sheet gauge and, therewith, the final strength (Fig. 44). Furthermore, the hot band determines the formability and anisotropy of the final sheet, which is important because of the heavy forming operations accompanying can making (Fig. 43).^[101–105] Plastic anisotropy due to the crystallographical texture of the sheet gives rise to the formation of an uneven rim of the can during

Fig. 43 Production sequence of drawn and wall-ironed “DWI” cans and can ends

Table 5 Chemical composition of alloys used for can production (wt.%)

AA designation	Si	Fe	Mn	Mg	Cu	Cr
AA3004	0.3	0.7	1.0–1.5	0.8–1.3	0.25	
AA3104	0.6	0.8	0.8–1.4	0.8–1.3	0.05–0.25	
AA5042	0.2	0.35	0.2–0.4	3.0–4.0	0.15	0.1
AA5182	0.2	0.35	0.2–0.5	4.0–5.0	0.15	0.1

deep drawing and ironing operations (Fig. 35, “Anisotropy” section). When cups are deep-drawn from circular blanks cut from a textured sheet, the plastic flow properties vary with the angle α around the sheet. Therefore, the flow of metal will be uneven and gives rise to the formation of an undulating rim with a number of high points, known as “ears,” and an equal number of low points, known as “troughs.” Highly uneven cup rims are detrimental for the transport of the can bodies and affect the whole process when ears are stretched and clipped off during ironing, leading to machine downtime reducing efficiency. Thus, the amount of earing must be minimized in can body stock production to ensure the optimum performance of the can-making processes.

The characteristic cube texture of a recrystallized hot band generates four ears at 0° and 90° to the former rolling direction, whereas a cold-rolled sheet with the

Fig. 44 Effect of the level of cold rolling on yield strength $R_{p0.2}^{[106]}$

typical β fiber rolling texture will develop four ears at $\pm 45^\circ$. Figure 45 illustrates how earing in stock can be minimized by controlling the texture such that both texture components are mixed. As already mentioned earlier, multistand hot rolling produces a recrystallized hot strip with a strong cube texture, which, during deep drawing, generates four $0^\circ/90^\circ$ ears. The quite slow rotation of cube-oriented grains toward the stable rolling texture β fiber and the resultant mixture of both texture components efficiently balances these opposite effects.

Fig. 45 Influence of (a, b, c) hot band textures with different degrees of recrystallization and, consequently, different fractions of the cube texture ($\{111\}$ pole figures) on anisotropy in (d) hot strip and (e) final cold-rolled can body stock (symmetrized earing profiles). A decrease in hot band temperature results in incomplete recrystallization with less pronounced cube recrystallization texture. Accordingly, the 45° ears in the hot strip are increased at the expense of the desired $0^{\circ}/90^{\circ}$ ears, which, on cold rolling, results in too strong 45° earing profiles. (Courtesy of Dr. P.Wagner, Hydro Aluminium Deutschland GmbH.)

Incomplete recrystallization at too low coiling temperatures leads to a hot band with a less pronounced cube texture but stronger rolling texture components (Fig. 45a and b). Consequently, there is a tendency to form 45° ears in the hot band (Fig. 45d), which is further enhanced during subsequent cold rolling (Fig. 45e). Complete self-annealing is achieved only at coiling temperatures in excess of 300°C . Otherwise, additional hot band annealing or interannealing treatments must be applied. On the other hand, at too high rolling temperatures, recrystallization may occur between rolling passes, which also reduces cube texture intensity.^[106] Thus, for maximum cube texture—as

necessary for optimum earing properties at final gauge—an optimum combination of hot rolling process parameters is required, which is best achieved in multistand hot rolling lines.^[107]

By cold rolling, the final material properties are reached. As illustrated in Fig. 44, for a 2.2-mm hot strip with a fully recrystallized microstructure, the required final yield strength in excess of 275 MPa (H19) is reached only at cold rolling reductions of as much as 80–90% and a finished gauge thickness below 0.5 mm. For a partially recrystallized or unrecrystallized hot strip, this level is reached sooner, but as outlined earlier, because of the

less pronounced cube texture in the hot strip, the acceptable level of 45° earing in the cold-rolled sheet is reached at too low rolling degrees (Fig. 45).

Another factor affecting finish gauge strength is the cold rolling temperature, which, under industrial rolling conditions, may rise up to as much as 150°C, significantly reducing cold rolling strength by recovery reactions. Likewise, any further heat treatment will give rise to recovery and/or recrystallization and, hence, will affect final material properties. For instance, in subsequent paint bake annealing operations, a certain decrease in strength is implied due to the recovery processes involved. Thus, such processes must be integrated in a complete description of final strength effective in the product application.^[107]

In conclusion, the production of such an apparently simple object as the aluminum beverage can requires a very detailed knowledge of the deformation and recrystallization mechanisms of the corresponding materials as well as a sophisticated control of the main processing parameters.

Brazing Sheet

Up to the 1970s, radiators and other heat exchangers for vehicles were manufactured from copper and copper alloys. In order to utilize the lower weight of aluminum alloys, brazing techniques suitable for aluminum have since been developed. Today, aluminum alloys are most commonly used in heat exchanger applications, including radiators, heater cores, oil coolers, as well as evaporators and condensers in air-conditioning devices.^[108–111] Figure 46a shows a typical modern car radiator with a brazed core made of different aluminum alloys in tubes, end plates, side plates and fins, and a plastic tank on each side. The plastic tank is mechanically fastened to the core by bending the outer rim of the end plate. New development is focused toward the development of fully recyclable all-aluminum heat exchangers (e.g., Fig. 46b). This design requires both good formability and high mechanical strength of the end plate material. The brazing of aluminum is most often performed using sandwich material in which the core alloy—usually a 3xxx Al–Mn alloy or, less frequently, a 6xxx

Fig. 46 (a) A typical modern car radiator with a brazed core made of different aluminium alloys in tubes, end plates, side plates and fins, and a plastic tank on each side. (Courtesy of AKG Autokühler, Germany.) (b) Prototype of an all-aluminum car heat exchanger (Courtesy of Behr, Germany)

Al–Mg–Si alloy—is clad with a thin layer of a braze with a lower melting point, typically a near-eutectic Al–Si alloy of the AA4xxx series containing 7.5–12.5% Si (Fig. 47a). The cladding alloy melts during brazing and accumulates at inward bends in order to minimize the surface tension (Fig. 47b).

Semifinished products of brazing alloys are produced through conventional hot and cold rolling processes. The core alloy is clad with a layer of 5–10% thickness of the core either on one or on two sides with the filler. The sandwich of as-cast ingot plus—mechanically joined or welded—clad is preheated, with the temperatures involved depending on the demands regarding final grain size. Heating of the ingots to about 500°C gives a coarse grain size because alloying elements such as Mn will essentially remain in solid solution. Thus, there is a large supersaturation of Mn, which, during the following steps of thermo-mechanical processing, will give rise to finely dispersed precipitates that interfere strongly with the progress of recrystallization. Homogenization at a temperature of about 600°C for 10 hr and hot rolling at 500°C will give rise to fairly coarse precipitates and, consequently, result in a material with a much smaller grain size. The heated sandwich is introduced into the rolling mill, where the connection between core and clad material is achieved by roll bonding during the first hot rolling passes. The material is hot-rolled to a thickness of 3–7 mm and then cold-rolled to final gauge. The material may be delivered soft-annealed (temper O), or back-annealed (temper H22, H24, or H26). Interannealing may be performed at a suitable sheet gauge for materials to be delivered in the cold-rolled tempers: H12 (=1/4 hard), H14 (=1/2 hard), or H16 (=3/4 hard).

Besides the technological factors affecting brazeability, a necessary metallurgical condition for good brazeability is that the core material is recrystallized, preferably with a reasonably coarse—or rather strongly elongated—grain size. When the as-received material is not yet recrystallized, it must be ensured that the core recrystallizes during the brazing cycle, well before the braze reaches its melting temperature (550–590°C). A coarse-grained structure is

Fig. 47 Section through a brazing material. (a) Core material, AA3005, one-side plated with a 10% layer of AA 4045 after a simulated brazing cycle. (Courtesy of Dr. R. Sicking, Hydro Aluminium Deutschland GmbH). (b) Cross-section of the joint between a tube and a fin in a brazed car radiator (Courtesy of Dr. H.-E. Eckström, Sapa Technology)

required to prevent the silicon in the cladding from diffusing along the grain boundaries into the core material (Fig. 48) and to improve sagging resistance. Loss of silicon due to diffusion would give rise to an increase in the melting temperature of the filler material, together with a reduction in its ability to flow and to form joints.

All parts of the heat exchanger must have good corrosion resistance in the environment where it is used. A radiator in a car, for example, should sustain the salt and wet atmosphere on the roads in northern countries without any extra corrosion protection. Special alloys have been developed for that reason. In general, silicon penetration into the core is also detrimental to the corrosion resistance, which means that the grain size should be large.

Another important consideration is mechanical strength of the brazed parts. Saving vehicle weight by downgauging is an important issue for car manufacturers, resulting in a demand for alloys with higher mechanical strength. However, most of the usual strengthening methods of common Al alloys cannot be used, either because the alloying elements would interfere with the brazing process, or because of the temperatures imposed during the brazing cycle. For instance, the solidus temperature of the core material must be at least 10°C higher than that of the filler (i.e., typically higher than 600°C). With regard to age-hardenable alloys, the cooling down from brazing temperature is too slow to allow for good age hardenability. As mentioned earlier, the grain size of brazing alloys must be large; hence, the only means to increase mechanical strength are solute and, particularly, dispersion hardening. Therefore, the common brazing alloys of the AA3xxx series alloys contain up to 0.5% Fe and 1–1.5% Mn (e.g., AA3103 and AA3005). The most modern method for brazing, controlled atmosphere brazing (CAB), uses a flux that is only capable of operating for alloys with maximum Mg concentrations of 0.3%. Alloys with higher Mg contents, including AA6xxx series alloys such as AA6063, have to be brazed under vacuum or with—very expensive—special Cs-containing fluxes. Additions of Cu and Zn are limited because they lower

the melting point of the core material. However, with concentrations of a few tenths of a percent, both elements can be used to adjust the corrosion potential of the various components of a heat exchanger.

In order to enable one to produce the rather complex shaped parts of a heat exchanger, the material must have good formability. Although forming of parts is usually made before brazing, some ductility is needed when the brazed parts are joined to other parts of a radiator using mechanical joining. To obtain good formability, the grain size should be small, whereas high amounts of alloying elements added to increase mechanical strength tend to decrease the ductility. This means that a compromise must frequently be made among optimal brazability, formability, and mechanical strength after brazing.

Aluminum Sheet for Car Body Panels

The demands for weight reduction in automotive construction led to increasing interest in sheets made from aluminum alloys for autobody applications so as to increase fuel efficiency and reduce vehicle emissions.^[111–118] Two types of Al alloys are being used, the nonheat-treatable Al–Mg (or Al–Mg–Cu) alloys of the 5xxx series and the heat-treatable alloys of the 2xxx (Al–Cu) and 6xxx (Al–Mg–Si) series. The main requirement for automotive sheets is to have a good formability such that complex panels can be stamped at economical rates. The 5xxx series alloys stand out by very good formability, but have relatively poor strength, and they suffer from strain markings during forming.^[100] Therefore, they are generally used for interior structural applications. The heat-treatable alloys, on the other hand, achieve their final strength only during the automotive paint bake cycle. Thus, they combine the good formability of the solution-treated state (T4 temper) with the increased service strength of the age-hardened state (T6 or T8 temper). Therefore, these alloys are superior for automotive skins where high dent resistance is required. Originally, the 2xxx series (e.g., alloys AA2008, AA2010, and AA2036) were most frequently used, for instance, as inner and outer hood panels for the Lincoln Towncar. However, these alloys suffer from poor corrosion resistance and merely offer a limited hardenability at the usual paint bake temperatures, so that their strengthening potential cannot fully be exploited.

For that reason, in the last years, the interest in 6xxx series alloys has increased markedly. The 6xxx series alloys contain magnesium and silicon, both with and without additions of copper. Compared with 5xxx and 2xxx alloys, sheets made from 6xxx series alloys stand out by good formability, good corrosion resistance, and sufficient strengthening potential during standard paint bake cycles. The 1991 Honda NSX all-aluminum sports car was built from a combination of sheets made from 5xxx series alloys for the body skeleton and the inner parts of

Fig. 48 Penetration of silicon from the cladding into the core material (Courtesy of Dr. H.-E. Eckström, Sapa Technology)

Fig. 49 Parts made from Al alloys in the Audi A8 with space frame technology (Courtesy of Audi, Germany)

the doors, hood, and trunk, and 6xxx sheets for the outer panels. In 1994, the Audi A8 was introduced as the first series vehicle with an aluminum space frame (ASF) technology, giving it a weight reduction of 40% compared with a corresponding steel body (Fig. 49). The outer panels are made from the alloy AA6016 supplied by Alusuisse, Switzerland (now Alcan International). Since 2000, the new compact-size Audi A2 has been available, which relies on a more advanced second-generation space frame.

The potential 6xxx alloys that may be used for autobody sheets include AA6009, AA6010, AA6016, and AA6111; recently, alloy AA6181A was introduced for recycling aspects (Table 6). These alloys are formed in the soft, naturally aged T4 condition and then harden during paint curing. In the United States, AA6111 is often used for outer panels in gauges of 0.9–1.0 mm. Alloy 6111 combines high strength and, hence, high dent resistance with good formability. However, due to the high copper content, 6111 may show susceptibility to filiform corrosion, although a study of recovered hang-on parts showed good performance after many years of service.^[119] In Europe, 6016 is typically selected in gauges of around 1–1.2 mm. Alloy 6016 gives superior formability to 6111, has better filiform corrosion resistance, and allows flat hems even on parts with local predeformations of more than 10%. However, the bake-hardened strength of 6016 is significantly lower than that of 6111.

In commercial production of AA6xxx sheets, the material goes through a specific thermomechanical treatment before reaching the final gauge. Property control depends on most of these process steps individually as well as in

rather complex interactions. In preparation for the hot rolling, the DC-cast ingots are scalped and then preheated to a temperature between 480°C and 580°C, in a cycle which may last up to 48 hr. During the preheating, the material is homogenized, short-range segregations are removed, and soluble phases are dissolved. The hot ingots are then transferred to the rolling line, which typically consists of a reversible breakdown mill where the ingots are rolled in a number of passes to a transfer gauge of 25–40 mm, followed by a high-speed multistand tandem mill where the thickness of the slab is reduced in three or four steps to a strip with a thickness between 3 and 6 mm at a defined exit temperature. The hot band is coiled and allowed to cool before it is cold-rolled to its final gauge of around 0.9–1.2 mm. The cold-rolled sheet is then unwound from the coil and passed single-stranded through a continuous annealing line. In this line, the material is rapidly heated to temperatures between 500°C and 570°C to dissolve the hardening phases and then quenched to retain the major alloying additions in solid solution; concurrently, the as-deformed material recrystallizes. Finally, the annealed sheets are precoated and/or prelubricated before being supplied for blanking and stamping.

The final in-service strength of the manufactured parts is only achieved after the forming operations through age hardening, preferably during the final automotive paint baking. This is at variance to the non-age hardening 5xxx series alloys that lose part of their strength during paint baking due to recovery reactions. The complex temperature/time cycle during a typical paint bake cure may be simulated through annealing for 20–30 min at about 180°C. At this temperature, the standard 6xxx car body sheet alloys would reach peak strength only after several hours, so finished body panels would be employed in a heavily underaged condition (Fig. 50). Therefore, the bodies of the first generation Audi A8 were subjected to a separate bake-hardening annealing for 30 min at 205°C to achieve extra strength. Conversely, this means that the aging response of the car body sheet alloys had to be tailored so as to give optimum results during the paint bake cycle. High levels of magnesium, copper, and silicon increase both T4 strength and, in particular, the bake-hardening response of 6xxx series alloys.^[117] Prolonged solutionizing times, increased temperature, and accelerated quenching rates all result in better age hardenability, yet at the cost of formability.^[115] The bake-hardening

Table 6 Chemical composition (wt.%) of the most important AA6xxx alloys used for automotive sheets

Alloy	Mg	Si	Cu	Fe	Mn	Zn	Ti
AA 6009	0.4–0.8	0.6–1.0	0.15–0.60	<0.5	0.2–0.8	<0.25	<0.1

AA6181A	0.6–1.0	0.7–1.1	<0.25	0.15–0.5	<0.4	<0.3	<0.25

Fig. 50 Warm age-hardening response of alloy AA6016 as a function of the aging time t for different aging temperatures and pretreatments (Courtesy of Dr. E.Brünger, Hydro Aluminium Deutschland GmbH)

response can be improved considerably using a pre-aging treatment, which may consist of an interrupted (two-step) quenching, extra preannealing, or retrogression.^[120,121] A slight predeformation of a few percent prior to warm aging also accelerates the age-hardening response (Fig. 50). However, a full scientific understanding of the underlying processes is still lacking due to the complexity of the precipitation reactions in the Al-Mg-Si(-Cu) system, and this is an area of considerable current interest.^[116,122]

An important consideration for sheets that are to be used as outer panels for car body applications is surface appearance after sheet processing and forming operations. Effects such as orange peel, strain markings in sheets of 5xxx series alloys, and the appearance of so-called paint brushes lines in 6xxx series alloys may prevent the use of such parts for exterior automotive applications. Orange peel can be avoided by controlling final grain size at levels

below around 50 μm . Strain markings in 5xxx alloys can be reduced by keeping the grain size above a certain limit, by quenching the material after the final recrystallization anneal (O-temper), by prestraining, or, in theory, by changing the temperature and strain rate during forming. The appearance of paint brushes lines in 6xxx alloys—commonly referred to as ridging or roping—has been linked to the presence of bands of similar orientation in the sheets.^[123,124] Figure 51a shows an optical micrograph of AA6016 in condition T4 after anodical oxidation, displaying strong texture banding. The texture bands result in surface roughening, which, in severe cases, can be unacceptable for paint finish and may degrade forming limits.^[125] In Fig. 51b, a roughness plot after 20% tensile deformation perpendicular to the rolling direction is displayed, which reveals the roping tendency. Bands of similar crystallographical orientation tend to deform collectively under the formation of elevated or depressed bandlike regions. Thus, in order to avoid roping, the texture sharpness of the sheet in T4 temper needs to be weakened using appropriate processing schedules. In conventional processing lines, cooling of the hot band is accompanied by heavy precipitation of fine dispersoids, mostly Mg_2Si precipitates (Fig. 52). These dispersoids may strongly interfere with the progress of recrystallization during the final solution annealing.^[126] Accordingly, control of the thermomechanical hot rolling is an essential tool in optimizing the texture and, ultimately, the surface appearance of 6xxx sheet material.

Thus, age-hardening Al alloys of the 6xxx series offer a great potential for substituting steels in automotive body panels. With a detailed understanding of the microstructural development and the resulting properties during sheet production, the thermomechanical processing can be optimized to produce sheets of high and stable quality as required for the high demands in sheet metal forming operations.

Aluminum Foil Products for Packaging

The intrinsic properties of aluminum, in particular its impermeability and barrier properties, together with its high level of corrosion resistance and high formability, make Al foil an excellent material for packaging applications. Al foil offers excellent barrier properties to light, ultraviolet rays, water vapor, oils and fats, oxygen, and microorganisms. When used to package sensitive products such as pharmaceuticals or food, aluminium is hygienic, nontoxic, nontainting, and retains the product's flavor. A very thin layer of Al foil—in some cases only 6.35 μm —can render a packaging laminate completely light-proof and liquid-tight. Al foil has been in use in the packaging of foodstuffs for some 70–80 years since it was first

introduced to replace tin foil in the linings of tea chests and to wrap chocolate bars. Recent statistics published by the European Aluminium Foil Association (EAFA) have shown that in 2000, the demand for aluminium foil continued to increase to 682,000 tons, representing a growth rate of more than 4%.

Foil products include a wide range of final gauges and applications. In general, foil is defined as rolled and annealed Al product with thickness below 150 or 200 μm . Foils for food containers are about 40–100 μm thick, lidding foils are between about 30 and 40 μm , with household wrapping and cooking foil between 10 and 20 μm . The thinnest foil, used to wrap chocolates and cigarettes or in packaging of liquids, may be only 6–7 μm thick. This so-called “converter foil” is used in a laminated form with paper, plastics, and/or lacquers, with the lamination process being termed as “conversion.”

By far, the largest demand for Al foil comes from the packaging industry. Packaging applications may include a wide spectrum of products, such as “ready meals” and catering, dehydrated foods (soups, sauces, pasta, etc.), preserved foods and other sterilized products (including pet foods), confectionery products, liquid products (long-life drinks, single-use portions, etc.), dairy products (milk, yogurt, butter, cream, cheese), and bottle necking and decorative labels (see Fig. 53a). Besides food packaging, aluminium foil is used extensively in the packing of tobacco products, cosmetics, and pharmaceutical products, either unsupported or in multilayered combinations (“blister foil”; see Fig. 53b). The remaining quantities of Al foil—on the order of 25%—goes into heat exchangers for cars (“Brazing Sheet” section), air conditioning, insulation, cable wrap, and other technical applications.

For most foil applications, commercial purity aluminum is used, which consists of more than 99% Al with additions

Fig. 53 Use of Al foil for packaging of (a) food products and (b) pharmaceuticals products (Photographs from Hydro Aluminium Deutschland GmbH)

of up to 0.8% Fe and about 0.25–0.3% Si. In the fully annealed condition (O-temper), such commercial purity Al of the AA1xxx series, including the well-known variants AA1050 and AA1200, have rather low strength. Higher strength—to allow for downgauging, for example—may be achieved through increased levels of Fe, for instance in the 8xxx series alloys such as AA8079. Al foil is produced in two different ways, either starting from a conventional DC cast ingot, which is hot-rolled to a strip of about 2–5 mm, or from a 6- to 7-mm-thick sheet produced by continuous casting routes (twin roll casting or belt casting).^[127] This strip is then cold-rolled to an intermediate (foilstock) gauge of about 0.4–1 mm, followed by annealing, typically in the temperature range 350–400°C. Then, the material is cold-rolled to final foil thickness. To achieve thinner foil gauges below, say, 100 µm, closed gap rolling must be used, which is performed in a dedicated foil mill. In order to increase productivity and to reduce the risk of damaging the extremely thin foils, in the last rolling step, typically below 40 µm, the foil is doubled so that two layers of foil are passed through the rollers together. That is why these foils have a brightly polished surface, which is imparted by the rolling cylinders on one side, whereas the other side has a matte finish. Most Al foil products will be used in the O-temper, which means that the foil must finally be soft-annealed. In addition to the recrystallization, the final gauge annealing is required to remove rolling lubricants from the foil.^[128]

The ratio of ductility and strength at the final gauge largely depends on the solution/precipitation state of the alloying elements Fe and Si. For processing reasons, the solute level must be kept low. This means that there is a limitation to the amount of strengthening through solid solution hardening, but the dominant strengthening mechanism is dispersion hardening with some contribution from solutes.^[128–130] Hence, the volume fraction and the size distribution of the dispersoids are an important factor in dispersion strengthening. Grain size has a relatively small influence on strength, but largely impacts ductility, with finer grain size giving higher ductility. Thus, to achieve a good balance of strength and formability in the final gauge product, recrystallization to a fine, uniform grain structure is required.

The recrystallization mechanism at final gauge is dependent on the level of cold reduction.^[55,127] At low to moderate strains, recrystallization occurs in a discontinuous manner (i.e., by nucleation and growth; (“Nucleation” section). In such cases, the final grain structure will be governed by particle-stimulated nucleation. At the high rolling reductions of thin gauge foils, however, continuous recrystallization may occur during annealing (“Extended Recovery and Continuous Recrystallization” section), promoting a fine grain structure.^[47,127]

The size distribution of dispersoids and the levels of elements in solid solution are also important in controlling the development of grain structure during final annealing.

Dispersoids will tend to refine the grain structure by inhibiting boundary movement during recrystallization. Solute elements will inhibit recovery, which generates recrystallization nuclei, thus tending to increase grain size.

For many packaging applications, burst strength is a requirement (i.e., the product must be resistant to splitting and puncture when in use, for example, as a wrapping or as a container lid). Burst strength is dependent on both the tensile strength and ductility, as well as the gauge.^[131] For wrapping applications, low springback is necessary to impart the so-called “dead-fold” characteristics, and this is achieved by using the alloy in the relatively soft, fully O-temper.

For converter foil, the mechanical requirements are related not to the end application in the laminated form, but rather to the lamination process itself. Again, tensile strength and ductility are important to minimize the number of strip breaks occurring through tearing during the conversion process and to allow the laminator to operate at higher tensions to avoid wrinkles in the laminate.

Obviously, the fortuitous combination of properties—especially its high formability and sufficient strength, together with excellent barrier properties—renders aluminum a very suitable material for packaging applications. With a variety of alloys and tempers plus a range of thicknesses varying from as little as 6.5 µm up to an (defined) upper limit of 0.2 mm, Al foil may be used in numerous ways to package goods such as food, dairy products, pharmaceuticals, or industrial products.

Design of Forming Processes: Sheet Metal Forming

T. Wanheim

Technical University of Denmark, Lyngby, Denmark

Abstract

This article addresses sheet metal deformations processes and are classified as secondary processing methodologies. Sheet metal forming processes are further classified as processes with: compressive stresses, tensile stresses, compressive and tensile stresses, bending, and shear. Additional discussion on sheet metal processing includes: process metallurgy and microstructure, process design, processing parameters, prevention of failures, formability and testing, and modeling.

Keywords: Bending; Deep drawing; Hardening; Roll forming; Stretching.

SHEET METAL DEFORMATION

This chapter, dealing with sheet metal deformation processes, is closely connected with the chapter on bulk deformation. Much of the necessary basic information has been given there, so for many aspects a reference to the text in this part will be sufficient. The method of description of the area of sheet metal forming will follow the layout of the description of bulk metal forming (Chap. 1) to avoid confusion.

Therefore it is recommended that the reader goes through Chap. 1 before reading the present part.

As already mentioned in Chap. 1, sheet metal forming is, from a practical and industrial point of view, considered as a parallel to bulk metal forming but in many cases completely different. The plane stress situation normally present in sheet forming compared to the three-dimensional stresses in bulk forming has been a classical criterion for defining sheet metal forming, but also the differences in tooling and machinery have lead to this distinction. Bulk forming machines are heavy things, often designed for large forces and product weights. Sheet forming machinery is often designed for very bulky products and the press tables are often large, forces can be low in comparison to bulk forming, and tool loads and stresses are relatively light in comparison. Much bulk forming belongs to the group of primary processes, but almost all sheet metal forming is in the group of secondary processing.

However, the distinction between bulk forming and sheet forming, understandable as it is, leads to uncomfortable contradictions. Bending of a wide sheet is a plane strain process, and bending of a narrow bar is very close to a plane stress process. Bending of sheet is considered as sheet forming, and bending of a narrow bar is bulk forming, even if the continuum mechanical treatment of the two is highly interrelated.

A rolling mill producing hot slabs or profiles in steel is considered a bulk forming machine, which seems right, but what about a rolling mill producing sheet for car industry or even producing aluminum foil for domestic use?

Deep drawing of a 1–2 mm sheet into a cup is clearly a sheet process even if the strain and stress situation is extremely complicated with large strains in the thickness direction. If the work piece is thick with a small diameter, e.g., for forming the first step in a sequence for shell manufacturing, the process is considered as a bulk forming process.

The manufacture of coins is normally considered a bulk process, but changing the lower tool into a leather cushion to produce bracteates with only one hard tool as it was carried out in the middle ages for lower denominations changes the process into a sheet process.

The classic division of metal forming processes in bulk and sheet forming is certainly not satisfactory from a mechanistic point of view, but is nevertheless very difficult to avoid from an industrial point of view.

CLASSIFICATION OF DEFORMATION PROCESSES

As stated in the chapter on bulk forming, classification can be performed in several ways as a general principle. The conventional way of basing the classification schemes on temperature, flow behavior, and stress state holds, of course, but some expansion and modification has to be performed.

The classification schemes based on temperature, flow behavior, and stress state have already been discussed in the bulk forming chapter and will not be repeated here.

The most rational way to classify forming processes and especially sheet metal forming processes is to follow

the German DIN system for process classification, which is basically a stress state system. It should be noted that in the German system, there are three main groups: forming, separation and joining, also called mass preserving processes, mass reducing processes, and mass increasing processes.

Only sheet material processes belonging to the main group forming will be described below.

The main subdivisions within this group are processes with predominantly compressive stresses, processes with combined compressive and tensile stresses, processes with predominantly tensile stresses, processes with bending, and processes with shear.

This will be treated in some detail below.

Processes with Compressive Stresses

To this group belong processes where the flow in the deformation zone mainly is established by a compressive load from the surroundings. The group is dominated by processes from the bulk forming area, as, e.g., extrusion, forging, and plate rolling. However, some sheet forming processes can also be included in this group. Examples are:

- Stretching.
- Dome forming.
- Cold heading of cups.
- Flanging.
- Coining.
- Necking-in.
- Edge rolling.
- Bulging.

Processes with Compressive and Tensile Stresses

To this group belong processes where the flow in the deformation zone is established by a combination of tensile and compressive stresses. A large part of the sheet metal forming processes belong to this group. Examples are

- Deep drawing.
- Rubber forming.
- Hydro mechanical deep drawing.
- Spinning.
- Ironing.

Processes with Tensile Stresses

To this group belong processes where the flow in the deformation zone is mainly caused by tensile stresses from the surroundings. Also, this group contains many sheet forming processes. Examples are:

- Stretcher Leveling.
- Stretch forming.

- Bulging.
- Expanding.
- Beading.
- High energy rate processes.

Processes with Bending

To this group belong processes where the flow in the deformation zone is caused by a bending moment, created either by external compressive or tensile loads or by external moments. Examples are:

- Air bending.
- Die bending.
- Folding.
- Rollbending.
- Rollforming.
- Roller flanging.

Processes with Shear

To this group belong processes where the flow in the deformation zone is caused by shear forces or moments from the surrounding tool. This group is not of any significance in sheet forming, and will not be further treated here. It must be mentioned that cutting, punching, blanking, nibbling, etc., are processes that are based on shear stresses, but because they belong to the main group ("separation"), they will not be treated here.

TYPES OF SHEET METAL FORMING PROCESSES

Processes with Compressive Stresses

Stretching

In this process, a sheet metal work piece is shaped by stretching one of its sides by means of hammer blows or by notching with a wedge-shaped tool (Fig. 1a,b). The process, which is very flexible, can be carried out as well by hand as in special machinery.

Fig. 1 (a) Plane stretching; (b) three-dimensional stretching

Dome Forming

In this process, a dome is formed from a sheet metal blank by local stretching made by multiple blows from a rounded hammer-shaped tool (Fig. 2). The process, which is very flexible, can be carried out as well by hand as in special machinery.

Cold Heading of Cups

In this process, the rim of a cup is reduced in length and increased in thickness with the aid of two counteracting tools (Fig. 3).

Flanging

In this process, a flange is formed on a hollow component by means of a punch and a die (Fig. 4).

Coining

The manufacture of coins, tokens, etc., can be considered as well a sheet metal forming process as a bulk process. The process takes place in special presses and highly loaded tools, often with a ring around the upper and lower coining tool, to increase the hydrostatic pressure in the process and to improve the coining precision (Fig. 5).

Necking In

In this process, the open-end diameter of a hollow component is reduced (Fig. 6).

Fig. 2 Dome forming

Fig. 3 Cold heading of cups

Edge Rolling

In this process, the edge of a sheet or a sheet component is rolled back upon itself, usually by means of a punch and guide to give rigidity or a better appearance to an article (Fig. 7).

Fig. 4 Flanging

Fig. 5 Coining

Fig. 6 Necking in

Fig. 7 Edge rolling

Bulging

In this process, an outward channel is formed in a hollow component by the application of axial pressure to the rim of the wall (Fig. 8).

Processes with Compressive and Tensile Stresses

Deep Drawing

This process, or rather group of processes, is one of the dominating manufacturing methods in sheet metal forming. Several types can be identified.

Deep Drawing without a Blank Holder This simple version of deep drawing uses only a die and a punch (Fig. 9). The maximum drawing ratio β (or Limiting Drawing Ratio, LDR), defined as the ratio of the largest diameter of the blank that can be drawn without failure to the diameter

Fig. 8 Bulging

Fig. 9 Deep drawing without blank holder

of the punch ($\beta = D_{\text{blank}}/d_{\text{punch}}$), will be around 1.3, and the process limitation will be wrinkles in the flange.

It is often favorable to shape the contour of the die as a tractrix. The rim of the flange is in this case very stable against tangential compressive stresses. If the ratio between the punch diameter and the sheet thickness is below 40, drawing ratios up to 2.8 are possible. Other benefits are:

Simple press system (no blank holder force, only punch movement).

Easy to combine with ironing steps in the same punch movement.

Good surface quality.

Less lubrication troubles.

The drawbacks are:

Long punch travel.

Somewhat complicated manufacturing of the die.

Almost exclusively limited to axisymmetric geometries.

Large thickness variations in cup wall.

Drawing ratio must be above a certain value.

Conventional Deep Drawing In conventional deep drawing, the tool system consists of punch, die, and blank holder. Figure 10 shows the principal layout of a conventional deep drawing. The blank can be divided into three zones, as shown. The outer annular zone X consists of material in contact with die and blank holder. The annular zone Y is at the beginning of the process neither in contact with the punch nor the drawing die. Zone Z is in contact with the punch nose.

In the drawing process, zone X is pulled in toward the profile radius of the drawing die by the radial tensile stresses. The blank holder has to keep the sheet from wrinkling caused by the circumferential compressive stresses during the decrease of the blank diameter. These stresses also result in increase of the thickness of the outer part of the blank.

Fig. 10 Principal layout of a conventional deep drawing

When the material in zone X passes over the die radius, it will become thinner because of the simultaneous stretching/bending and stretching/unbending. The inner part of zone X will undergo a further thinning because of the tensile stresses between punch and die.

Zone Y will undergo bending, unbending, and sliding under tension over the die radius, pure stretching between punch and die, and bending and sliding under tension over the punch nose radius.

Finally, zone Z undergoes stretching and sliding over the punch nose. The thinning is dependent on the geometry, the friction, and of course the tensile load from the drawing process.

Thus in zone Y, there is a narrow band under pure tension between two bands of combined bending and stretching. This will result in a thicker band between two circular bands with necking A and B (Fig. 11), showing the thickness variations (exaggerated) in a cylindrical cup with flat and hemispherical head, respectively.

As a simple approximation, one can assume that there is no net thickness change from the blank to the finished cup, and simple geometrical considerations then give for the height to diameter ratio, h/d , of a finished flat-bottomed cup:

$$h/d = 1/4(\beta^2 - 1) \quad (1)$$

Several different processes in the blank can be identified during the transformation from blank to cup:

Pure radial drawing and sliding against tools on outer annular area.

Pure radial drawing between die and blank holder.

Bending when entering die radius.

Sliding against die radius combined with continued radial drawing.

Unbending in exit of die radius.

Stretching between die and punch.

Bending over punch profile radius.

Sliding over punch profile radius.

Stretching and sliding over punch nose.

Fig. 11 Thickness variations (exaggerated) in deep-drawn cylindrical cup with flat and hemispherical head

Deep Drawing of Circular Blanks

1. Calculation of maximum drawing force. The maximum drawing force $P_{z,max}$ can be calculated by the following formula, which is based on the slab method used on the separate elements of the process described above.

$$P_{z,max} = \pi d_m t [B(A + C) + D] \quad (2)$$

where

$B = e^{\mu\pi/2}$	is the contribution from friction in the die radius
$A = 1.1\sigma_{0.1} \ln(d_{p,max}/d_m)$	is the contribution from the ideal plastic work in flange
$C = 2\mu P_{BH}/\pi d_{p,max} t$	is the contribution from the blank-holder friction
$D = t\sigma_{0.2}/2\rho_{die}$	is the contribution from the bending/unbending at the die radius

In these expressions, the following symbols are used:

D_0	is the original blank diameter
$d_m = d_1 + t$	is the middle cup diameter
d_1	is the punch diameter
t	is the sheet thickness
μ	is the coefficient of friction at die radius and at outer rim of blank
$d_{p,max}$	is the diameter of the blank when maximum drawing force is reached This is dependent on the strain-hardening properties of the sheet. Thus for a drawing ratio of 2, $n = 0.1$ gives $d_{p,max}/D_0 = 0.94$ and $n = 0.5$ gives $d_{p,max}/D_0 = 0.79$.
$\sigma_{0.1}$	is the mean yield stress in the flange between rim and start of die radius
$\sigma_{0.2}$	is the mean yield stress in the die radius curvature
P_{BH}	is the blank-holder force
ρ_{die}	is the die radius

2. Calculation of blank holder pressure. The blank holder can be of one of three types:
Constant gap blank holder for single-action presses.
Spring-loaded blank holder for single-action presses.
Pneumatic or hydraulic blank holder for single-action presses.
Outer ram activated blank holder for double-action presses.
The most common type for serious production is the outer ram activated blank holder.

The thickness increase described above means that only an outer annulus of the blank will carry the load from the blank holder, and the friction from this will result in a back-pull acting against the tensile

stresses originating from the drawing process. Therefore the main part of the blank is not in contact with the blank holder.

The right pressure is found as the minimum pressure necessary for preventing wrinkles in the blank. As a rule of thumb, the blank-holder force is about 1/3 of the drawing force.

The blank-holder pressure p_{BH} and the blank-holder force P_{BH} are given by the following two equations:

$$p_{BH} = (2 - 3) \times 10^3 \left[(\beta - 1)^3 + 0.5 \times 10^{-2} \times D_0 / t \right] \sigma_{UTS} \quad (3)$$

where

$$P_{BH} = p_{BH} A_{BH} \quad (4)$$

A_{BH} is calculated as the area of the sheet covered by the blank holder, even if the actual area of contact as mentioned is much smaller and limited to the rim of the blank.

3. Tooling geometry. If the profile radius of the drawing die is larger than 10 times the sheet thickness, the influence on the drawing force is rather small. The drawing force will increase for decreasing radii as a consequence of the increased bending and unbending strains. Radii substantially larger than 10 times will increase the tendency to wrinkle.

The profile radius of the punch is important as the fracture always occurs at the lower neck (B in Fig. 11). For a constant blank diameter, a larger radius gives a smoother increase in the drawing force and a longer punch travel, but the maximum drawing force is un-changed. A larger profile radius will also give an increased thinning of the bottom of the cup.

The clearance between the punch and the die is normally chosen to 10–30% in addition to the sheet thickness, as the outer zone of the blank has an increased thickness. If the clearance is too small, the blank may be sheared or pierced by the punch.

4. Material and lubrication. The stress-strain curve of the sheet material is important. A high strain-hardening exponent results in that the maximum drawing force is reached later in the process than for a low exponent. A low exponent will mean lower load at the punch nose and consequently that the thinning of the bottom of the cup decreases; in other words, a high exponent will give better drawing ratios. Anisotropy, treated later in “Isotropy and Anisotropy,” is important for deep drawing, as explained there. Lubrication is important for the process, and if possible the blank should be lubricated where it slides against the die and against the blank holder, and not where it touches the punch, where no sliding is wanted.

Deep Drawing of Square and Oval Components When deep-drawing circular components, the deformation is evenly distributed around the axis. This is not the case when deep-drawing square and oval components. Here the highest strains are located at the corners, and lower strains are found along the side walls. It is possible to apply the rules for drawing of circular components to the drawing of noncircular parts by replacing the punch and the blank areas by circles of equal size and calculating their respective equivalent diameters $d_{punch/eq.}$ and $D_{blank,eq.}$

$$d_{punch,eq.} = 2 \left(A_{punch} / \pi \right)^{1/2} \quad (5)$$

and

$$D_{blank,eq.} = 2 \left(A_{blank} / \pi \right)^{1/2} \quad (6)$$

Drawbeads are often used to control the flow of the blank into the die cavity. A draw bead is typically a small oblong obstacle shaped like a small half cylinder, built into the blank holder or the die surface to increase the local stresses needed to pull the sheet into the die cavity. It can also be shaped as a step in the common contour between die surface and blank holder. Beads restrict the flow of the sheet metal by bending and unbending it during drawing.

Draw beads also help to reduce the required blank-holder force, because the beaded sheet has a higher stiffness and hence a lower tendency to wrinkle.

Redrawing A typical maximum drawing ratio can be $\beta = 2$, which means that a blank with a diameter of 200 mm can be drawn into a cup with a diameter of 100 mm and a height of around 75 mm. To produce a cup with a larger ratio of height to diameter, one or more redraws are required.

The methods for redrawing falls into two main groups: direct redrawing and reverse redrawing.

Direct Redrawing The tooling for direct redrawing is different from the first drawing tool (Fig. 12a, b). In Fig. 12a, the blank has to go through two sequences of right angle bending and unbending. This is not so severe in Fig. 12b, where the die is made conical with an angle of 30–45°, and the blank holder, which fills out the drawn cup, consequently has a conical nose. The redrawing punch slides in the blank holder in the process.

Several redrawing steps can follow each other, but the drawing ratio in these steps must decrease because of the strain hardening. The resulting drawing ratio can be written as:

$$\beta_{tot} = \beta_1 \cdot \beta_2 \cdot \beta_3 \cdots \beta_n \quad (7)$$

Resulting drawing ratios up to about 6 can be reached without annealing for deep-drawing qualities of steel sheet.

Fig. 12 (a) Direct redrawing, right-angle tool; (b) direct redrawing, conical tool; (c) reverse redrawing, separate tool; (d) reverse redrawing, combined tool

For a component having to undergo many redraws, a low strain-hardening exponent is advantageous unless interstage annealing is introduced. This is contrary to the situation where only one draw is necessary, where a high strain hardening helps to prevent excessive thinning of the bottom of the cup.

Reverse Redrawing In reverse drawing, the original inner side of the first drawn cup becomes the outer side after the reverse draw. If the tool has the geometry shown in Fig. 12c, only one bending and unbending is necessary. The two

draws can be carried out in the same operation, as the punch from the first draw acts as die ring for the reverse draw, as shown in Fig. 12d. This of course gives reduced tool costs.

Rubber Forming I (Guerin Process)

In this process, a rubber pad constitutes the one half of the usual die set (mostly the female part) and plays a universal role in that it adapts to different shapes of the counterpart (Fig. 13). The advantage is the inexpensive tooling; the disadvantages are high press forces and the limited life of the rubber pad, which, depending on the severity of the operation, may not endure beyond about 20,000 pieces. This makes the process interesting for small batch production. Polyurethanes are normally used because of their resistance to abrasion, their resistance against being damaged by sharp edges or burrs, and their long fatigue life. The rubber pad is either a solid block or is consisting of several slabs cemented together, and it is contained in a steel housing. The advantage of cementing rubber slabs together is that different hardness can be used in different layers, normally the hardest closest to the forming surface. A wear pad is often used, placed on the blank before the pressing. The thickness of the total pad must be about 30% greater than the height of the form block.

Rubber Forming II (Marform Process)

In the Marform process, deep-recessed parts with either vertical or sloped walls can be formed. The blank is held against the rubber pad by a blank holder, through which a punch is acting as in conventional deep drawing (Fig. 14). A controlled pressure is applied on the blank holder during the process, whereby a pressure from the rubber is exerted between the partly drawn cup and the punch. The resulting

Fig. 13 Rubber forming, Guerin process

Fig. 14 Rubber forming, Marform process

friction allows deeper draws to be carried out, and the blank-holder pressure will give a component free from wrinkles.

Rubber Forming III (Hydroform Process)

In the hydroform or fluid form process, a controlled hydraulic pressure is acting on a rubber diaphragm covering the blank (Fig. 15). In this way, a more uniform pressure can be obtained and more severe draws can be achieved than by the other two methods.

Hydromechanical Deep Drawing

In hydromechanical deep drawing, a hydraulic pressure squeezes the partly drawn cup directly around the punch (Fig. 16). This results again in an unloading of the tensile stresses around the punch nose and thereby a considerable increase in the possible drawing ratio. The process can be used for very complicated geometries.

Spinning

The group of spinning processes involves the forming of axisymmetric parts over a mandrel with tools or rollers.

Fig. 15 Rubber forming, hydroform process

Fig. 16 Hydromechanical deep drawing

There are three basic types of spinning processes: conventional spinning, shear spinning, and tube spinning. The spinning machines are from a kinematic point of view similar to lathes, but the static and dynamic properties are very different, the main difference being that in a lathe the tangential (normally vertical) force is an order of magnitude larger than the radial force, this being reversed for a spinning machine.

Conventional Spinning In conventional spinning, a circular blank of flat or preformed sheet material is held against a mandrel and rotated while a rigid tool deforms and shapes the material over a mandrel (Fig. 17). The tools may be activated manually or by a computer-controlled hydraulic mechanism. The process involves a sequence of passes and requires considerable skill. The process is particularly suited for conical or curvilinear shapes in relatively small batches. As the particles of the blank are drawn into smaller radii, the wrinkling problem is serious. The process is normally carried out at room temperature, but spinning at elevated temperatures is used, e.g., for low-ductility or high-strength materials. Very large parts, with diameters up to 6 m, are formed this way.

Fig. 17 Conventional spinning

Shear Spinning In shear spinning, axisymmetric conical or curvilinear components are formed by reducing the thickness and maintaining the diameter of the blank (Fig. 18). If the geometry is correct, this means that no radial displacements are present, and consequently no circumferential stresses are introduced. From this follows, for instance, that a conical shape can be spun on a square blank without dimensional changes or distortions in the plane of the blank. Components for space technology and military use are produced this way. Parts up to 3 m in diameter can be produced.

Tube Spinning In tube spinning, the thickness of a cylindrical part is reduced by spinning it on a cylindrical mandrel using rollers (Fig. 19). The process can be carried out with the rollers working internally as well as externally. Superficially, the process resembles an ironing or an extrusion process, but it should be noted that the repeated deformations after each revolution, where the roller has moved horizontally because of the feed, is closer to a stepwise open-die forging. Tube spinning is used to make pressure vessels, automotive components, jet engine, rocket, and missile parts.

Ironing

A drawn cup will normally have a nonuniform thickness distribution in the wall. To create a uniform wall thickness

Fig. 18 Shear spinning

Fig. 19 Tube spinning

and to increase the height of the cup, the cup is normally pushed through a die using a punch in an ironing process (Fig. 20). The clearance between punch and die determines the wall thickness of the cup. The cup can go through several ironing processes, sometimes in the same stroke. Ironing can also be directly carried out in the drawing process by controlling the clearance.

As there is practically no diameter change, the ironing process can often be regarded as a plane strain process in an analysis, e.g., using the slab method. The ironing process resembles the plane strain drawing of a flat strip, and the same approach is used, just remembering that the friction in strip drawing is acting backward on both sides of the strip. In an ironing process, the friction against the die is still acting backward, but as the cup elongates and the punch remains undeformed, the friction between punch and cup is opposite to that between cup and die. If the friction on the inside is higher than the friction at the outside, friction can actually help in obtaining high reductions in the ironing process.

Processes with Tensile Stresses

Stretcher Leveling

In stretcher leveling, the sheet or strip is straightened with tensile forces between jaws (Fig. 21). For discussion, see the paragraph on tensile testing of strips.

Stretch Forming

In the stretch forming process, a metal sheet is formed by the application of tensile loads to the material to produce the required shape. The sheet is clamped in jaws at both ends and stretched into plastic condition over a forming

Fig. 20 Ironing

Fig. 21 Stretcher leveling

tool as shown in Fig. 22a, b. Two versions of the process are used: stretch forming and stretch-wrap forming. In the stretch forming process, the tool moves into the clamped sheet as shown; in stretch-wrap forming, the sheet is first stretched beyond the plastic limit and then wrapped over the form block as shown. The process is used to produce body parts for aircrafts, trucks, cars, and rocket motor housings, where the geometry has rather gentle shape and is free of sharp bends.

The advantages of stretch forming are:

Only one die is needed.

The die can be made of inexpensive material.

Contours with compound contours are possible.

Spring back is almost absent.

The stretching and resulting sliding at the interface between die and sheet causes friction, and consequently the tension in the sheet will vary from a maximum at the jaws and gradually decreasing inward against the sliding direction.

If we let

R = local radius of curvature at element in consideration

$d\theta$ = center angle covering element

ds = length of the sheet-die interface for the element

T = varying tensile force in sheet for unit width

T_0 = tensile force at A for unit width

T_B = tensile force at B for unit width

p = normal pressure in interface

μ = friction coefficient in interface

the force equilibrium in the radial direction gives (Fig. 23):

$$p = T/R \quad (8)$$

Fig. 22 (a) Stretch forming; (b) stretch-wrap forming

Fig. 23 Element in stretch-forming process

the force equilibrium in the tangential direction gives:

$$dT/T = -(\mu/R)ds \quad (9)$$

and combining and integrating gives:

$$\ln(T_B/T_0) = -\mu \int_A^B (1/R)ds \quad (10)$$

The right-hand side of the above equation can be numerically evaluated for any given die contour.

As shown later in the discussion on bending, spring back is a problem for pure bending. If tensile stresses are superimposed, the neutral line will move toward the concave side of the bend. If those tensile stresses become so large that the neutral line disappears, i.e., the outer side as well as the inner side of the bend are deformed in tension, the spring-back problem is almost eliminated, which is an important advantage for stretch forming processes.

Bulging

In the bulging process, the internal diameter of a hollow component is increased by the use of a fluid or elastic medium. The main process limitations here are instability or local thinning, described in "Instability in Tension" (Fig. 24). Bulging can also be performed by spinning, described under processes with combined tensile and compressive stresses. The mentioned process limitations originating from the tensile stress situation do not apply there.

Expanding

In this process, the diameter of the open end or another part of a hollow component is increased (Fig. 25).

Beading

In this process, an outward (beading) or inward (necking in) channel in the wall of a hollow component by the operation of shaped matching rolls is produced (Fig. 26).

Fig. 24 Bulging

Fig. 25 Expanding

Fig. 26 Beading

High-Energy Rate Processes

A small group of nonconventional processes attracted much interest in the 1960s and 1970s where explosives, electrical discharges, and magnetic fields were used to shape domes in sheet blanks and bulges on tubes often using water as a energy-transmitting medium. They are playing insignificant roles in modern production technology.

Processes with Bending

Bending of Bar and Sheet with Pure Moment

It is necessary to distinguish from the very beginning the difference between bending of a narrow bar and bending of a wide sheet. Figure 27 shows an element of a bar subjected to a moment M_z . The bar will be deformed into a curved shape, where the outer fibers necessarily have to be stretched and the inner fibers will be compressed. Somewhere in the middle, there must then be a layer that is neither stretched nor compressed. This layer is called the neutral line, and with this line as border, the tensile forces and the compressive forces are in equilibrium. In a bar, there will not be any restraint for sideways deformation, and therefore one can compare the elements above the neutral line with tensile specimens and the elements below with elements subjected to compression. The material originally above the neutral line will as a whole be stretched and thinned, and below the neutral line it will undergo longitudinal compression and sideways expansion. Therefore the situation in bending a narrow bar is with good approximation one of plane stress. Obviously, this situation will lead to a piling up of material below the neutral line and a thinning of material above this line. Therefore the sides of the bar will start to tilt inward toward the “stretch” side, and as a consequence a curvature at right angles to the bending curvature will appear on the upper and lower surface of the bar. This curvature, concave at the top and convex at the bottom, is called the “anticlastic curvature.”

As there always must be static equilibrium in longitudinal direction, this piling up of material on the inner side of

Fig. 27 Element of a bar subjected to plastic bending by pure moment (a) seen from the side; (b) seen from the end; (c) deformed shape

the bend and thinning of material on the outer side means that the neutral line has to move downward as the bending proceeds.

Bending of a wide sheet is somewhat different. The piling up of material below the neutral line has to happen without relief in sideways flow because of the width of the sheet, so only a thickening of the compressive zone can happen, except, of course, for very narrow zones close to the edges, where some lateral deformation is possible. The neutral zone will have to move downward all the same. The main thing to remember is that the bending of a wide sheet basically is a plane strain process, and that the bending of a narrow beam is a plane stress process.

Strains, Stresses, and Moments in Sheet Bending

The strains in the length direction x of the sheet will be proportional to the distance from the neutral line, and as value for the engineering strain in the x direction one obtains in the distance y from the neutral line:

$$\epsilon_x \left((R+y)d\theta - R d\theta \right) / R d\theta = y/R \quad (11)$$

or, for the logarithmic strain:

$$\epsilon_x = \ln(1 + (y/R)) \quad (12)$$

where R is the radius of the neutral line and y is the distance of the element from the neutral line.

If the sheet is totally in the elastic state, the stresses in the x direction are expressed by

$$\sigma_x = E(y/R) \quad (13)$$

as shown in Fig. 28a. For increasing moment, the outer fibers will start to yield first, and if we assume a non-hardening material for simplicity, the plastic zone will gradually spread inward as shown in Fig. 28b, c.

From this, it is easy to show that the necessary moment for elastic bending is:

$$M_E = (1/6)bh^2\sigma_x \quad (14)$$

Fig. 28 Stress distribution in bending of a sheet, elastic-nonhardening plastic material. (a) Elastic state. (b) Elastic-plastic state. (c) Fully plastic state

and the moment necessary for full plastic condition is:

$$M_p = (1/4)bh^2\sigma'_0 \quad (15)$$

σ'_0 being the yield stress in plane strain, $\sigma'_0 = (2/\sqrt{3})\sigma_0 = 1.15\sigma_0$.

Residual Stresses and Spring Back

As shown above, the necessary external moment to load the sheet to full plastic condition can be expressed by:

$$M_p = (1/4)bh^2\sigma'_0 \quad (16)$$

If this moment is released, the sheet will straighten somewhat. This will happen as an elastic unloading, i.e., equivalent to a stress linearly changing through the thickness of the sheet (Fig. 29). Assume that the associated, imaginary, elastic stress distribution reaches the value σ_A in the outer fibers of the sheet.

This moment of elastic unloading M_A must be equal to the plastic moment of maximum load, which means:

$$M_A = M_p \quad (17)$$

or

$$(1/6)bh^2\sigma_A = (1/4)bh^2\sigma'_0 \quad (18)$$

giving:

$$\sigma_A = (3/2)\sigma'_0 \quad (19)$$

The residual stresses are found as the difference between the elastic and the plastic stress distribution. The outer sixth on the top of the sheet will end up with compressive residual stresses with the maximum value:

$$\sigma_{\text{res,max,top}} = -1/2\sigma'_0 \quad (20)$$

Fig. 29 Unloading of bent sheet. (A) Assumed elastic unloading stress distribution. (B) Resulting residual stress distribution

and the lower part of the sheet has tensile residual stresses with the maximum value:

$$\sigma_{\text{res,max,top}} = +1 / 2 \sigma'_0 \quad (21)$$

The release of the moment that was used in the bending process and the resulting elastic unloading will result in an opening of the bent angle. This is called the elastic spring back.

The derivation is somewhat lengthy, but if we set

α = bending angle before spring back

α' = bending angle after spring back

$\alpha = 0$ before bending

R = neutral bending radius before spring back

R' = neutral bending radius after spring back

$$\beta = 2\sqrt{3}(1 - \nu^2)(\sigma'_0/E)(R'/t)$$

we can write

$$\alpha = \alpha'(1 + \beta) \quad (22)$$

$$R = R'/(1 + \beta) \quad (23)$$

Position of the Neutral Line

As earlier stated, the neutral line has to move inward, toward the concave side of the bend. For a sheet, where the width can be assumed constant from convex to concave side and plane strain can be assumed, the slab method used on a curved sheet will give

$$R = (a/b)^{1/2} \quad (24)$$

or

$$R/a = (1 + t/a)^{1/2} \quad (25)$$

where

R = neutral radius

a = inner radius

b = outer radius

t = sheet thickness

Bending Allowance

The position of the neutral line is not only of academic interest. It is deciding for a very important parameter in bending jobs: the bending allowance.

If the convex (male) part of a bending tool has the radius of a , it is clear that if the finished component has to satisfy tolerances in its final shape, one must know where the neutral line is positioned in order to design the process and the size of the original blank properly. From the drawing, one can read the tool dimensions, but a sheet with a thickness t will bend along a curvature that is determined

of the position of the neutral line where the length of the bent part does not change. One simple suggestion is of course just to add half of the sheet thickness to the radius a , and calculate the necessary blank size from this. But as we have seen, the neutral line does not stay in the middle of the original sheet thickness, it moves inward. This simple suggestion will then give too large blanks for the final component.

Several suggestions have been forwarded, but the problem is rather complicated, among other things because there will be a theoretical discontinuity between the unbent part of the component, where the neutral line of course stays nicely in the middle of the sheet thickness, and the curved part, where the neutral line has moved from this position. This geometrical discontinuity does not exist in reality, but is evened out in different ways, among other things depending on the strain-hardening characteristics of the material.

The given expression in Eq. 24 is a good choice for the calculation of the neutral radius.

Air Bending

In this process, a tool, typical the upper tool in a press brake, is causing a bend of a sheet without any forming support from the lower tool (Fig. 30).

Die Bending

In this process, a female die is used together with the male die to give better tolerances to the bent profile. The final stage of the process is often a calibrating force exerted between the dies (Fig. 31).

Fig. 30 Air bending

Fig. 31 Die bending

Folding and Wiping

In these bending operations, one part of the sheet is clamped and the free part is moved in a folding motion by a forming tool (Fig. 32a, b).

Roll Bending

In this process, a cylindrical component is produced from a sheet by passing it between three staggered rolls (Fig. 33).

Roll Forming

This process is the shaping of a (often complicated) long profile by passing a strip material from a coil through a number of forming rolls (Fig. 34).

Roller Flanging

This is the production of a flange on a hollow component by means of two shaped opposing rolls (Fig. 35).

Fig. 35 Roller flanging

PROCESSING ASPECTS

Temperature

The basic considerations of temperature are given in Chap. 1. The differences between sheet forming and bulk forming are determined by the large differences in the surface/volume ratio between the two types of processes, meaning that as bulk forming processes as a rule can be considered as adiabatic, but in the case of sheet metal forming one has to be more careful. A deep drawing of a thin cup in a brass alloy could be considered as isothermal, but the same process carried out with a titanium alloy (low density, high strength) could be close to adiabatic.

Some processes can be improved by a temperature increase. For instance, in a deep-drawing process, the drawing ratio can be increased by heating the flange of the blank through the die and blank holder and keeping the punch cold.

Spinning processes can be carried out hot. Difficult alloys can be formed in heated tools, in the so-called isothermal processes.

Strain

The basic considerations have already been given in the bulk forming chapter. One important aspect will be mentioned here, namely the relatively uncomplicated method of measuring strains in sheet metal forming processes. Because of the almost uniform strain distribution through the thickness of the sheet in most sheet forming processes, strain can be experimentally determined with the aid of a grid on the surface of the specimen put on by, e.g., photographic, serigraphic, or etching techniques. If the strain is not uniform, as, e.g., in bending processes, strain distribution through the thickness can normally be easily calculated on the basis of the surface strains. The grid is applied

on the flat sheet before the process, and measured on the deformed workpiece, either after the full process or after selected steps.

The normal grid pattern is a system of circles with small diameters, touching each other or slightly over-lapping. The circles will deform into ellipses, and the magnitude and the directions of the principal strains can be found by identifying the major and minor axes of the ellipses.

If D_0 indicates the original diameter of the circle and $D_{\max}$ and $D_{\min}$ are measured as the maximum and minimum diameters of the ellipse after forming, their directions will give principal strain direction, and the values $\ln(D_{\max}/D_0)$ and $\ln(D_{\min}/D_0)$ will give the two principal strains in the surface of the sheet. The thickness strain can then be calculated from volume constancy.

Strain Rate

This has been covered in the bulk forming chapter.

Stress

This has been covered in the bulk forming chapter.

Friction

This area has been described in the bulk forming chapter. Because of the comparatively low interface pressures between tool and sheet specimen, the Coulomb friction law is most often used. Experimental methods for determining friction coefficients will be discussed in “Friction Tests” section

Yield Criteria—Isotropic and Anisotropic

For simple analyses, the von Mises or Tresca criterion discussed in Chap. 1 can be and have been used. These criteria describe isotropic materials. For some approaches in sheet forming, a compromise between the Tresca and the von Mises criterion is used. This happens, e.g., in the classical derivation of maximum drawing force in deep drawing, where the yield stress in the flange is set to $1.1 \sigma_0$.

As explained later, the rolling process, which is the basis for sheet metal production, creates anisotropy, i.e., different properties in different directions. The accepted criterion assumes three mutually orthogonal planes of symmetry throughout the material; the lines of intersection of these planes being called the principal axes of symmetry. The rolling direction, the transverse direction, and the thickness direction are as a rule considered principal axes of symmetry.

The definition and experimental determination of anisotropy will be discussed later in the text. If it is necessary to bring anisotropy into plasticity calculations, the more complicated Hill anisotropic yield criterion should be used replacing the von Mises criterion shown in Eq. 20 of Chap. 1.

The Hill criterion is written as

$$\sigma_0 = \left[(3/2)/(F + G + H) \right]^{1/2} \left[F(\sigma_2 - \sigma_3)^2 + G(\sigma_3 - \sigma_1)^2 + H(\sigma_1 - \sigma_2)^2 \right]^{1/2} \quad (26)$$

reducing to the von Mises criterion for $F = G = H$.

Determination of the constants is discussed later in this chapter.

Hardening

This has been covered in Chap. 1.

DESIGN ISSUES TO PREVENT FAILURES

Geometrical and Mechanical Issues

The description of this in Chap. 1 is mainly relevant for three-dimensional flow in bulk specimens under compressive stresses, but is applicable in general terms to sheet metal forming. However, some additional remarks are necessary.

The main problem with sheet metal forming processes is that neither too large tensile stresses nor too large compressive stresses in the plane of the sheet are acceptable. This seems a paradox when one considers the multitude of process alternatives in sheet forming, but probably the large number of different processes is a consequence of the rather narrow windows in stresses and strains that are at hand in this process group.

Tensile stress and strain leads to local thinning and eventually cracks, and compressive stresses in the plane of the sheet can lead to buckling or wrinkling. They are both phenomena constituting serious process limitations that should be avoided by clever tool-and-process design.

Because of the large surface-to-volume ratio in a typical blank, lubrication plays an important role in sheet metal forming, and may significantly change the flow. However, this can be used in a constructive way, using local application of lubricant, as discussed in the paragraphs on deep drawing.

Sliding lengths are often large, and therefore lubricant breakdown and resulting surface defects and local pick up can appear. This is often unacceptable because of the cosmetic requirements on, e.g., car parts. On the other hand, if the lubrication is too efficient or the surface is free, an orange-peel topography may appear, which is equally unwelcome. This is because of the unrestrained deformation of the individual grains according to their varying orientation and available slip planes.

Residual stresses are important, mainly because they are the origin of spring back, which is a large problem in sheet forming, necessary to cope with in the process design stage.

Metallurgical and Microstructure Issues

Most of the issues regarding metallurgy and microstructure are determined when the material goes through the primary processing in the casting, hot rolling, and cold rolling stages. The main considerations for sheet metal forming processes are given in the following paragraphs.

Anisotropy, discussed later in this chapter, gives rise to formability properties in drawing and stretching processes. Large plane anisotropy gives rise to the formation of ears in deep-drawing processes and consequently to uneven wall thickness distribution in the circumference of the drawn cup and material waste in the final trimming. On the other hand, a high value of the normal anisotropy is normally beneficial.

Strain hardening must be considered in each process. Normally, a high strain hardening will delay the moment of local thinning and instability and is thus beneficial, but in special cases, as redrawing without interstage annealing, a low strain hardening ratio could be preferable.

The upper and lower yield point in steel can give rise to easy-glide bands that appear as stretcher strains or Lüder's bands. They can be avoided by eliminating the upper yield point, by a slight reduction (2%) in temper rolling shortly before the forming process. Too long delay will give the carbon and nitrogen in the steel possibility to diffuse and thereby to recreate the upper yield point.

FORMABILITY AND TESTING METHODS

Definition

For bulk forming, the concept of workability has been discussed. Because of high tool stresses, large and inhomogeneous flow, risk for catastrophic shear, and internal and external cracks, a set of tests and workability definitions have been developed. The situation for sheet metal processes is different.

The tool stresses are typically lower than in bulk forming processes; internal catastrophic shear and internal cracking are normally exceptions and an external crack will normally be preceded by a local thinning. The prevalent plane stress situation in sheet metal forming processes means in broad terms that the process limitations are either caused by excessive compressive stresses or excessive tensile stresses in the plane of the sheet.

Tests

Testing of sheet material for sheet forming processes can broadly be divided into:

materials testing
simulative testing
friction tests

Materials Testing

Uniaxial Tensile Testing The uniaxial testing of a metal strip is mechanically carried out in the same way as the testing of a round specimen, the gripping jaws of course being modified. However, some very important differences have to be noted.

Isotropy and Anisotropy If a material is isotropic, it has the same value of its properties in all direction. An anisotropic material obviously then has different properties in different directions. One has to define which properties that are under consideration, a certain material could, e.g., be anisotropic from the point of view of strength, but isotropic if one considers thermal conductivity.

Because of the rolling processes, which are the basis for sheet metal production, anisotropy is a phenomenon that must be taken seriously in sheet forming. In the sheet rolling process, the material is deformed more or less under plane strain conditions, resulting in mainly thickness reduction and elongation. For calculation purposes of forces in wide sheet rolling, the influence of the width increase is normally neglected as a process phenomenon, and some average of the contact area is chosen.

For sheet material, a very well-defined sort of isotropy/anisotropy is defined with great importance for metal forming. This definition of anisotropy deals only with strains.

We will consider this phenomenon with a tensile test of a metal strip as reference.

The yield stress is:

$$\sigma_o = P/(wt) \quad (27)$$

and the principal strains are given by:

$$\epsilon_l = \ln(l/l_1) \quad (28)$$

$$\epsilon_w = \ln(w/w_1) \quad (29)$$

$$\epsilon_t = \ln(t/t_1) \quad (30)$$

where

P = tensile force read on the tensile testing machine

l = momentary length of the considered element

w = momentary width of the test strip

t = momentary thickness of the test strip

l_1 = original length of the considered element

w_1 = original width of the test strip

t_1 = original thickness of the test strip

For an isotropic material, the reduction in thickness is the same as the reduction in width, so $\epsilon_t = \epsilon_w$ and thus $\epsilon = -2\epsilon_t = -2\epsilon_w$ according to the equation of volume constancy:

$$\epsilon_l + \epsilon_w + \epsilon_t = 0$$

For an anisotropic material with different deformation properties in different directions, ϵ_t and ϵ_w will not be equal. The anisotropy of a sheet metal is normally determined by a tensile test and is calculated as:

$$R = \epsilon_w / \epsilon_t \quad 0 < R < \infty \quad (31)$$

If the tensile specimen keeps its width and all deformation happens as thinning, we obtain $R = \infty$, and if the specimen keeps its thickness and only width is decreasing, $R = 0$.

To describe the anisotropy of a sheet material, tensile tests in the directions 0° , 45° , and 90° to the rolling direction are carried out. $R = R(\alpha)$ normally has a maximum or a minimum for these angles. From this data, two values of anisotropy are defined, called normal anisotropy $\bar{R}$ and the plane anisotropy ΔR .

$\bar{R}$ is determined as a simple average of the R values in all eight 45° directions relative to the rolling direction. One obtains the following expression:

$$\bar{R} = (R_0 + R_{90} + 2R_{45})/4 \quad (32)$$

expressing the difference in ease of deformation between the average values in the plane of the sheet and the value normal to the sheet plane.

The plane anisotropy ΔR expresses the variation of R in the plane of the sheet. This is calculated taking the values in all eight 45° directions. One obtains the following expression:

$$\Delta R = (R_0 + R_{90} - 2R_{45})/2 \quad (33)$$

The practical importance of anisotropy is rather large, so a close control of a certain amount of anisotropy is beneficial. In deep drawing for instance, the anisotropy in the plane of the sheet, ΔR , will give ears on the drawn cup, resulting in waste of material and uneven wall thickness. One tries to reduce this anisotropy for this reason. The normal anisotropy, on the contrary, is beneficial, as it allows drawing of higher cups.

The constants in the Hill anisotropic yield criterion can be determined using tensile testing in three directions, σ_{01} , σ_{02} , σ_{03} determined in the rolling direction, transverse rolling direction, and normal to the sheet plane. This last determination can be performed by one of the compression methods described later.

One obtains:

$$2F = \sigma_{02}^{-2} + \sigma_{03}^{-2} - \sigma_{01}^{-2} \quad (34a)$$

$$2G = \sigma_{03}^{-2} + \sigma_{01}^{-2} - \sigma_{02}^{-2} \quad (34b)$$

$$2H = \sigma_{01}^{-2} + \sigma_{02}^{-2} - \sigma_{03}^{-2} \quad (34c)$$

Biaxial Tensile Testing Biaxial testing or bulge testing is carried out to investigate the behavior of a sheet material

subjected to tensile stresses in two perpendicular directions. It is normally carried out by clamping a circular disk of the sheet metal—a membrane—around its rim and subject it to an oil pressure on one side. The membrane will bulge and the strain can be measured the central region.

Biaxial Tensile Testing, Equal Straining If the membrane is circular, the test method is often called “balanced biaxial testing.” The strains and also the stresses in the central region can be determined if the strain, the bulge radius, and the oil pressure are measured during the bulging. The strain is measured with an extensometer, the curvature with a spherometer, and the oil pressure with a pressure gage. Extensometer and spherometer should be in one integrated unit. The relevant equations are:

$$\sigma_0 = p\rho/2t \quad (35)$$

$$\epsilon = 2 \ln D/D_0 \quad (36)$$

where

σ_0 = yield stress

ϵ = equivalent strain

p = fluid pressure

ρ = radius of curvature

t = sheet thickness

D = momentary distance between the extensometer contact points

D_0 = original distance between the extensometer contact points

The bulge will be unstable and start local thinning when $\epsilon = (4/11)(2n+1)$; that is, for a considerably higher strain than the uniaxial tensile test. For an n value of 0.25, representative for steel, the uniaxial tensile test will become unstable for $\epsilon = 0.25$, but the balanced biaxial test will give useful data up to $\epsilon = 0.55$.

Biaxial Tensile Testing, Unequal Straining If the circular die is substituted with an elliptic die, the strains will not longer be equal in the longitudinal and the transverse directions. The strain in the transverse direction will be larger than the strain in the longitudinal. With a circle grid etched or photographed on the surface, this can be used for formability measurements, as discussed later in *Formability Testing*.

Compression Test Two compressive tests for sheet material should be mentioned—the multiple layer upsetting test and the plane strain upsetting test.

Multiple Layer Upsetting Test The multiple layer upsetting test can be used as a substitute for the biaxial balanced tensile test, if the objective is to obtain stress-strain curves, but useless for experimental determination of instability.

However, this condition can be calculated in the actual situation from the experimentally determined value of n .

The test is useful when the sheet pieces are too small for a tensile test or a balanced biaxial test. It can give stress-strain curves up to considerably higher strains than the tensile tests.

The test is carried out by taking a number of small blanks possibly with a small hole punched in the center of the blanks and stacking them to a cylindrical slug of dimensions $1 < h/D < 1.5$. In a press or testing machine, the stack is then upset as a normal solid slug for bulk forming upsetting with measurement of force and displacement. The slugs are held concentric by a pin in the lower tool and the upper tool has a corresponding hole in it to accept the pin as the upsetting proceeds.

The test relies on that the strain condition in compressing a flat blank between frictionless tools is exactly the same as the condition in a balanced biaxial test. From Eqs. 14 and 20 in Chap. 1, it is seen that adding or subtracting the hydrostatic stress component σ_M [Eq. 16, Chap. 1] in the von Mises yield criterion does not influence the value of the yield stress.

In the uniaxial tensile test σ_M has the value $(\sigma_0 + 0 + 0)/3 = \sigma_0/3$; in the balanced biaxial test, the value is $(\sigma_0 + \sigma_0 + 0)/3 = (2/3)\sigma_0$; in the multiple layer up-setting test, the value of σ_M is $(-\sigma_0 + 0 + 0)/3 = -\sigma_0/3$.

This difference in hydrostatic stress component of $[(2/3)\sigma_0 - (-\sigma_0/3)] = \sigma_0$ will only have negligible influence on the stress-strain curve.

Plane Strain Compression Test The plane strain compression test (the Watts and Ford compression test) was originally developed to establish stress-strain curves for the rolling process.

Even if rolling is normally considered a bulk forming process, the test is developed for establishing the stress-strain curves for sheet material, and therefore should be mentioned here.

Two flat tools are pressed into a sheet strip that has a width w at least six times as large as the tool contact breadth a in order to secure a plane strain deformation (Fig. 36). The proportion between the breadth of the tool a and the thickness of the sheet h should satisfy the inequality $2 < (a/h) < 4$. The reason for this is the following:

If $a = h$, the upper bound field is a simple cross under 45° , similar to the slip line field shown in Chap. 1, Fig. 23. The necessary pressure at this moment is $p/\sigma'_0 = 1$ or 1.15 times the uniaxial yield stress.

The value of the yield stress in plane strain σ'_0 is often written $2k$.

When the compression starts, this “forging cross” will distort, and an upper bound model of the situation will just show a gradually flattening cross, as shown for the situation $(a/h) = 1.41$, when the upper bound model predicts a switch to two narrow crosses. The dimensionless pressure at this moment is $p/\sigma'_0 = 1.06$.

Fig. 36 Plane strain compression test

From here, the dimensionless pressure will decrease until the situation can be described with two right-angle crosses for $a = 2h$ and again giving $p/\sigma'_0 = 1$. The two crosses are gradually flattened until they, for the (a/h) value of 2.44, flip over from two wide to three narrow crosses. At this moment, $p/\sigma'_0 = 1.02$. The three narrow crosses go through the right angle geometry at $a = 3h$ and here again $p/\sigma'_0 = 1$.

The mechanism of flattening crosses and flip over to one cross more is repeated, and this shift from three to four occurs at $(a/h) = 3.46$ with a $p/\sigma'_0 = 1.01$.

To avoid the first pressure maximum, it is recommended not to start the test for $a = h$, but for $a = 2h$.

When a reaches $4h$, friction starts to play a role. As shown in Chap. 1 in the description of the slab method, the parameter constellation of μ (a/h) plays an important role in the determination of the contribution of friction to the measured pressure [see, e.g., Eq. 23 in Chap. 1]. In this case, forging between flat anvils in plane strain the dimensionless mean pressure can be written as:

$$p/\sigma'_0 = 1 + (\mu/2)(a/h) \quad (37)$$

A coefficient of 0.01, which is rather low and very difficult to obtain, and requires polished tools and careful lubrication will thus give an error of 2% for an $(a/h) = 4$.

In this way, there commended window of $2 < (a/h) < 4$ is determined.

In the testing process, one starts with a tool twice as broad as the thickness of the strip. This tool pair is used for the first reduction in compression to half thickness. Now the tool is exchanged to a second tool with half the breadth of the first tool, and compression goes on to $1/4$ of the original sheet thickness. Now a new tool with yet half breadth can be inserted and so on. Thus a plane strain compression test can be carried out keeping (a/h) between the recommended limits.

It must be remembered that the equivalent strain in this test must be calculated as

$$\epsilon = (2/\sqrt{3}) \ln(h/h_1) \quad (38)$$

and the uniaxial yield stress must be calculated as

$$\sigma_0 = (1/2\sqrt{3})(P/ab) \quad (39)$$

Here h_1 is the original thickness of the sheet and b is the width of the sheet.

Instability in Tension When treating sheet metal processes, where stresses are predominantly tensile, it is necessary to go a bit deeper into what happens at the point of necking in the tensile test than when treating bulk forming processes.

Instability in a Round Tensile Specimen For simplicity, we will start with reviewing the tensile testing of a cylindrical rod.

For this rod being tested in tension, the yield stress σ_0 increases but the cross-sectional area A decreases. The tensile force F can be written as

$$F = \sigma_0 \cdot A \quad (40)$$

At some point of the testing, the decrease of area wins over the strength increase, and at this moment the engineering stress-strain curve shows a maximum, (Fig. 12, Chap. 1). Here we have

$$dF = d(\sigma_0 \cdot A) = 0 \quad (41)$$

Constancy of volume V gives

$$dV = d(l \cdot A) = 0 \quad (42)$$

l being some defined length on the specimen.

At the maximum of the engineering stress-strain curve, we thus can write the following two equations:

$$\sigma_0 \cdot dA + A d\sigma_0 = 0 \quad (43)$$

$$l \cdot dA + A \cdot dl = 0 \quad (44)$$

which easily give

$$\sigma_0 / l = d\sigma_0 / dl \quad (45)$$

or

$$d\sigma_0 / d\epsilon = \sigma_0 \quad (46)$$

The importance of this equation becomes clear when it is combined with the power law hardening expression given in Eq. 21 in Chap. 1. One obtains:

$$d(K\epsilon^n) / d\epsilon = K\epsilon^n \quad (47)$$

or

$$\epsilon_{\text{instab}} = n \quad (48)$$

The value of the strain hardening exponent n lies between 0 for a non-strain-hardening material, where the instability

in a tensile test sets in immediately and 0.4/0.5 for very fast strain hardening materials. Steel and aluminum lie somewhere in the middle of this range annealed qualities having higher n values than work-hardened.

The fact that necking starts when the longitudinal strain reaches the value of n is a serious limitation for the use of tensile testing as a material test for forming operations. In the area of bulk forming, curves for strain hardening at higher strains can be obtained by upsetting of circular cylinders and measuring deformation force plus the axial deformation. The friction problems mentioned in Chap. 1 can be overcome by special measures, as, e.g., by the Rastegayev method, where a shallow depression in the end surfaces of the specimen are filled with, e.g., paraffin or stearin.

Another approach using tensile testing is to repeatedly use the wire drawing process and after each reduction cut a suitable length of the wire and subject this to a tensile test. Arranging the resulting stress-strain curves on a common strain axis, where the starting point for each curve is the accumulated strain up to that point, possibly with the addition of redundant strain, can give reliable stress-strain curves.

The same approach can be used in sheet metal testing using the rolling process + tensile testing of rolled strips instead of wire drawing. It has to be remembered that the rolling is carried out under plain strain conditions and the subsequent tensile testing under uniaxial conditions.

Instability in a Strip As in the case of the rod, the homogeneous deformation of a strip in tensile testing will only be possible as long as the strain hardening can compensate for the decreasing area. The decrease of area will invariably win this tug-o-war, and the deformation will change from homogeneous into necking with local deformation. The deformation will be concentrated in the neck, the deformation force will decrease and consequently the plastic deformation in the remainder of the test piece will stop. The necking will take the shape of a straight shallow ditch with the borders along a direction where no deformation exists. If the width was constant ($R = \infty$), this would be a straight line along 45° . However, for an isotropic material, the decrease in width will be equal to the decrease the thickness. Calculations show that this direction will lie under the angle $\phi = 35.3^\circ$ from horizontal if the tensile direction is vertical.

Obviously, the value of this angle will be dependent on the value of R .

It can be shown that:

$$\tan \phi = (R / (1 + R))^{1/2} \quad (49)$$

which gives the above angle for $R = 1$.

Instability of a Thin-Walled Sphere A hollow thin-walled sphere with wall thickness t and radius r is loaded

with an internal pressure p . Assume that the stress σ_r in the thickness direction is compressive and equal to $-p$. Along the shell surface, the stress is everywhere tensile and has the value $\sigma_\theta = \sigma_\varphi$. As no shear stresses exist, σ_θ , σ_φ , and σ_r must be principal stresses, θ and φ being two orthogonal directions in the shell surface.

Equilibrium of a small circular part of the shell surface gives:

$$p\pi r^2 = 2\pi r t \sigma_\theta \quad (50)$$

or

$$p = 2(t/r)\sigma_\theta \quad (51)$$

or

$$\sigma_r = -2(t/r)\sigma_\theta \quad (52)$$

If t/r is small, say 0.01–0.02, the influence of σ_r in the yield criterion [Eq. 14 in Chap. 1] is negligible and we can safely write:

$$\sigma_\theta = \sigma_\varphi = \sigma_o, \sigma_r = 0 \quad (53)$$

We will assume that the criterion for instability can be considered as $dp/d\epsilon = 0$.

This means that the sphere becomes unstable and keeps expanding when a certain inner pressure is reached, even if this is not further increased. Calculations will give:

$$d\sigma_o/d\epsilon = (3/2)\sigma_o \quad (54)$$

or, using the power hardening law:

$$\epsilon_{instab} = (2/3)n \quad (55)$$

Testing Conditions Care should be taken to carry out the testing in conditions as close to the process conditions as possible. This is not only relevant for strain rate but also for temperature, even if a process as well as tensile testing is carried out at room temperature. In studying the deformation of a titanium alloy sheet for a heat exchanger, it turned out that tensile testing in free air gave much too low yield stresses to be reliable in the process analysis. The reason was that the close contact between the thin titanium and the very large heat sink created by the pressing tool gave almost isothermal conditions, but the testing of the titanium strip in air resulted in a very hot specimen. Testing the strip submerged in a water container solved the problem.

Formability Testing A very important way of describing the deformative properties of a sheet metal is developed in the so called formability diagrams or forming limit diagrams (FLD). These diagrams are based on a plane coordinate system, where the abscissa shows the minimum

strain ϵ_{min} and the ordinate is ϵ_{max} (Fig. 37). Below the lower full line, no fracture will occur. Above the upper full line, fracture is certain. The first quadrant in the diagram describes conditions where ϵ_{min} and ϵ_{max} are both positive: There are tensile stresses everywhere in the plane of the sheet. This area is called the stretch forming area. Thus the balanced biaxial tensile test will be represented by a straight line going upward from origo under 45° (slope +1) dividing the first quadrant in two equal sectors.

In the fourth quadrant, the strains are of opposite sign, and this is called the draw forming area. Thus a pure isotropic tensile test will be depicted in a straight line through origo under 26.6° (slope -2).

The vertical axis $\epsilon_{min} = 0$ describes forming conditions (stretching) at right angles over a long ridge in the forming tool.

The strains are measured by a circle grid applied on the surface of the sheet to be tested, as described in “Strain” section. When a crack appears, the strains are measured and the coordinates marked in the diagram. Thus the points for the balanced biaxial test and the uniaxial test are easily found.

For intermediate points in the FLD curve, the elliptical biaxial test discussed in “Biaxial Tensile Testing, Unequal Straining” can be used.

A modification of the Erichsen test described in below (see “Erichsen Test”) can also be used. The conventional Erichsen test will give balanced biaxial condition on the top of the sphere, but if rectangular sheet specimens with smaller width than the ball diameter are used, condition between balanced biaxial state and uniaxial condition can be obtained. The ball diameter should be larger than in the standard Erichsen test.

Simulative Tests

The philosophy behind the simulative tests is that they in a simplified way are supposed to simulate different sheet metal forming processes and thereby facilitate the selection of the right material. The simulative tests are named after their initiators: Erichsen, Olsen, Fukui, Swift, Sachs, etc.

Fig. 37 Formability diagram

The two most well-known tests are the Erichsen test and the Swift test.

Erichsen Test The Erichsen test, schematically shown in Fig. 38, is a stretch forming test. A circular blank from the material that is going to be tested is clamped between a die and a blank holder with a force of 10 kN. A spherical punch is pressed down into the blank and the travel length of the punch before fracture occurs is measured. This travel length, measured in millimeter, is a characteristic property of the sheet metal: the Erichsen number. A high Erichsen number indicates a good “stretchability.”

Swift Test The Swift test, schematically shown in Fig. 39, is a deep-drawing test. A series of blanks with increasing diameters are cut out of the sheet metal in question. Blanks with steadily increasing diameters are deepdrawn, and at one point a diameter is reached, where the punch penetrates the not yet completely drawn cup. In this way, the maximum drawing ratio $\beta_{\max}$ is found. $\beta_{\max}$ is defined as the ratio between the largest blank diameter, $D_{0,\max}$, that can be drawn without fracture and the punch diameter d_1 . A high Swift number indicates a good “drawability.”

Friction Tests

The ring test described in Chap. 1, Sec. VI.B.4, can in principle be used for sheet metal forming, but as the thickness of the sheet normally is rather small, say 1–3 mm, the dimensions of the ring become very small. Furthermore, interface pressures between sheet and tool in sheet metal forming are normally below the yield stress because of the tensile stresses that as a rule exist in the plane of the sheet,

Fig. 38 Erichsen test

Fig. 39 Swift test

and sliding lengths in sheet forming operations are often large compared with the sliding lengths in the ring test. This test is consequently avoided in sheet metal friction testing.

Here two types of test are predominant, the plane strip tests without deformation and strip tests with bending under tension.

Strip tests without plastic deformation have been developed with varying geometry (Fig. 40). To avoid misleading results caused by the lubricant being scraped off by a sharp edge or caused by misalignment of the two sliding shoes, hinged versions have been used. If a back tension is applied, the friction coefficient changes.

For tests with bending under tension, two versions have been used: the die ring simulating test and the draw bead simulating test.

The die ring simulating test is shown in Fig. 41a, b. If the radius is small, a considerable amount of the measured drawing force is caused by the bending and unbending of the strip. This can be measured and subtracted by using a free rotating roll as die in a second experiment (Fig. 41b).

The draw bead simulating test is schematically shown in Fig. 42. It is one of the most used simulative tests in sheet metal forming. In the test, a strip of the sheet is

Fig. 40 Friction simulation tests without plastic deformation

Fig. 41 (a) Die ring simulative test. (b) Profile radius replaced by roller

Fig. 42 Draw bead simulative test

pulled through the draw bead simulator, and is going through several bending and unbending steps. This force has to be measured and separated by exchanging the fixed draw beads with free rotating rolls.

The drawing force and the tool separating force C has to be measured to determine the friction coefficient.

DEFORMATION MODELING METHODS

In Chap. 1, dealing with bulk forming processes, the main modeling methods have been described and there is no need to repeat that here. Because of the great variety of process configurations in sheet metal forming, all of them, the slab equilibrium, the slip line method, the upper bound method, and the finite element simulation, have been used. Early literature was much based on the slab equilibrium method because of the rather homogenous deformation in many of the processes, but slip lines and load bounding were also used. Interesting work has been performed using the slip line method to design the shape of the blanks for noncircular deep-drawing processes.

These “classic” approaches should not be neglected, as the feeling for the mechanics of the processes in a very high degree relies on them. The basic understanding created by these methods is extremely valuable whether the task is to select a process, design it, establish the diagnosis and the cure for failures in it, or it comes to designing experiments or appraising the results of a simulation.

At present, almost all process simulation and modeling is carried out using different FEM software packages, an area that in sheet metal forming really has been developing fast. Especially the development of, e.g., high-strength sheet materials, new nonferrous alloys, study of nonlinear strain paths, and the use of tailored blanks (laser-welded blanks with different material qualities, different thicknesses, etc.) have put very large demands on new software, and much work has been spent on the development of this.

The forming of high-precision miniature components has also stimulated this development.

Designing for Aluminum

Howard A. Kuhn

Scienda Building Sciences, Orangeburg, SC, United States

Abstract

In the design of aluminum forgings, the designer must specify the material and process and geometric details so that the component will meet performance requirements. Forging produces parts of high integrity because the process sequences refines and homogenizes metallurgical structure, elimination of material defects assuring maximum material strength. This article specifically addresses the following forging design considerations: material aspects, geometrical aspects, cost aspects, forging methods, process mechanics, and forged part design.

Keywords: Cost; Deformation; Design; Forging processes; Mechanics.

OVERVIEW

In the design of aluminum forgings, as with any product, the designer must specify the material and process (based on desired properties) and the geometric details (shape, dimensions, and tolerances) such that the component will meet performance requirements. From a concurrent engineering perspective, the product design decisions should exploit the flexibility offered by the process, but not exceed its limitations. While manufacturing the product to meet the designers specifications is the job of the production engineer, collaboration between designers and producers can avoid design features that are difficult or impossible to form, thus saving rework and redesign efforts, and reducing the time to product realization.

Almost without exception, forgings are specified when critical mechanical load transmission requirements are to be met. Aluminum alloy forgings are primarily used for structural parts on aircraft and land vehicles, but other applications include housings, casings, and linkages for a wide variety of mechanical systems. Forging produces parts of high integrity because the process sequences refines and homogenizes the metallurgical structure, eliminating material defects that cause premature failure and assuring that the material strength is at its peak level. The cost of producing forgings, however, is high because of the high skill level and time required for craftsmen to produce forging dies. While forgings constitute a small percentage of the total aluminum usage, their low numbers are outweighed by their importance in critical load transmission applications.

Material Aspects

Each material process leading up to, and including, the final forging step contributes to establishment of the final

metallurgical structure of the material, thereby determining its final in-use properties. Feedstock for forging operations are produced by casting liquid metal or by consolidating powder into ingots or billets. Large dendritic grain structures, porosity, and segregation characterize the microstructure of typical castings, and an oxide network (from the surfaces of the original powders) characterizes consolidated powders. Primary working processes, such as hot rolling, extrusion, or open die forging, break up the dendrites and close up the porosity in cast ingots, and break up and distribute the oxide network in consolidated powders. Additional hot working continues to refine the microstructure.

A common characteristic of hot working processes is grain flow, or alignment of inclusions and second phase particles in the direction of metal flow, or elongation. In rolling or extrusion, of course, the grain flow is in the longitudinal direction of the rolled or extruded shape. In the forging of complex shapes, however, the grain flow will be multi-directional, following the movement of metal in the elongated directions of each geometric feature. This alignment of inclusions and second phase particles has a strengthening effect in the direction of alignment, but is accompanied by a reduction of ductility in the direction transverse to the fiber orientation. Designers can use this effect to advantage by aligning the grain flow in the direction in which the part will experience the greatest stresses during use.

To achieve the highest level of mechanical properties in aluminum forgings, heat-treatable aluminum alloys are normally specified (2000, 6000, and 7000 series). These alloys are strengthened slightly during forging as the hot working reduces the grain size and, to a small extent, carries out precipitation hardening at the hot working temperatures. Optimum mechanical properties of the part are developed subsequently through heat treatment. In this

post-forging operation, the materials are solution heat treated at a temperature just below the solidus, then water quenched and artificially aged above room temperature for several hours.

Distortions of the part geometry may occur during heat treatment because of non-uniform cooling. This is largely due to adjoining geometric features that have different area to mass ratios. Whenever possible, the designer can minimize distortions due to heat treatment by avoiding designs that lead to non-uniform cooling.

Geometric Aspects

Forging of aluminum alloys is particularly applicable to producing precise, intricate shapes with good surface finish. The alloys are very ductile at hot working temperatures, and they do not develop scale during heating. In addition, the forging temperature is relatively low so the dies can be heated to nearly the same temperature as the workpiece, which prevents cooling of the workpiece and facilitates flow of metal into small cavities in the die.

However, there are limitations to the geometric complexity that can be obtained. During the forging process, force applied to the material by the forging equipment generates pressure that forces metal to flow into intricate cavities of the die. Long, thin die cavities require high pressure to force the material into them. If excessive pressures are required, the total forging load may exceed the capacity of the forging equipment. In addition, localized stresses in the die due to high pressure in the die cavities may become large enough to cause overloading failure of the die, fatigue cracking due to repeated loading, and rapid die wear in high metal flow regions. An additional limitation to shape complexity is the possibility of defect formation in the material during forging. In particular, as the material flows around small corner radii on the die (the result of small fillet radii in the part) or undergoes very large expansion of a free surface, laps and cracks may occur.

Cost Aspects

The cost of aluminum forgings depends strongly on the quantity of parts to be produced, shape complexity of the part, and the amount of machining required to reach the finished shape, dimensions, and tolerances. *Blocker-type*, *conventional*, *high definition*, and *precision* are the classifications, respectively, of forgings that are progressively closer to the final part geometries. Blocker-type forgings, which are only a rough approximation of the desired part shape, are produced with inexpensive, simple shape dies, but they require extensive machining to reach the final shape. In contrast, precision forgings use very expensive, complex dies, but they require little, if any, machining to reach the final part dimensions. Blocker-type forgings are economical for parts in small quantities, and precision

forgings are economical for producing large quantities of parts over which the high die costs can be amortized.

Process and equipment limitations also affect forging cost. Aluminum alloy billets are heated somewhat below their solidus temperature before forging because the heat generated during forging deformation causes a temperature rise in the material. If the initial billet temperature plus the temperature rise during forging exceeds the solidus, incipient melting of the material occurs, leading to severe cracking. This effect is particularly pertinent in high-speed forging, such as on a mechanical press or forging hammer, because the heat generated has little time to diffuse into the dies. This reduces the complexity of the shapes that can be produced on high-speed forging equipment, and potentially increases the amount of machining required. Thus, increasing the production rate by using a high speed forging operation also reduces the shape complexity that can be obtained and may increase the amount of machining required to reach the final shape.

Current Trends and Future Developments

While the majority of aluminum forgings are made from heat treatable alloys produced by ingot metallurgy, advanced alloys have been developed for specific property improvements. The aluminum-lithium series, for example, provides high strength and increased elastic modulus with reduced density. Premium strength alloys have also been developed by consolidating rapidly-solidified powders into forging stock. These alloys are particularly resistant to corrosion. Aluminum alloy matrix composites, reinforced with silicon carbide particulate or whiskers, provide improved strength over conventional aluminum alloys. All of these advanced alloys can be forged, requiring nearly the same forging pressure as conventional alloys, but some are less workable and prone to cracking during forging. In addition, forging of sintered aluminum powder preforms has recently become a commercial reality. The low workability of composites and powder preforms present new challenges to defect-free forging of aluminum parts.

Advances in the solidification science of aluminum have resulted in castings with reduced segregation and porosity, leading to improved properties. As a result, direct casting of complex shapes is a threat to the dominance of forgings for critical load transmission applications. In addition, the semi-solid forming process, based on thixotropic material technology, may further erode the markets for forgings. Semi-solid processes form billets heated to a mushy state (between its solidus and liquidus) in forging or die casting equipment. The resulting material has virtually no porosity and a fine microstructure, so it can compete with forgings on the basis of structural integrity. Parts formed by semi-solid processes, however, do not have the strengthening effect of grain flow that is a feature of solid state forming. High-speed machining of complex shapes directly from heavy rolled plates is an additional threat to expanded use

of forgings. Reduced set up time, machine tools of greater rigidity, precision computerized controls, and new cutting tool materials have made high speed machining a viable contender for producing complex shapes that are ordinarily made by forging.

The major deterrent to more widespread use of forging is the high cost and long lead time for the design and production of tooling. For this purpose, computer technology (CAD/CAM) is being used to expedite the design and manufacture of tooling. In addition, process simulations by finite-element modeling and physical modeling are being used increasingly by forging shops for the development of optimized process parameters, including tooling designs. This practice reduces the trial-and-error efforts required to produce successful forgings. Furthermore, rapid prototyping methods are being refined to produce tooling directly from CAD solid model files. This approach is being introduced to plastic injection molding and die casting, first, because of the lower pressures involved. One major advantage of the use of rapid tooling approaches is that internal cooling channels can be fabricated into the tooling, conforming to the part shape, and leading to much more uniform heating or cooling of the part. Collectively, these technologies will reduce the time and cost of producing forging tooling, and will alter drastically the way forging design and production is carried out in the next decade.

Rationale

To understand the design flexibility and limitations of aluminum forgings, we will review the current forging methods and materials, as well as the mechanics of metal flow during forging. These considerations will then lead to an understanding of the design guidelines for aluminum forgings.

FORGING PROCESS

Forging Methods

Blocker-type, conventional, and high definition approaches to forging (also known, collectively, as impression die forging) are very similar in that the tooling consists of an upper and lower die containing the negative impression of the part to be produced. A blocker-type forging, Fig. 1, produces only a rough approximation of the final part shape and dimensions, with large corner and fillet radii, generous taper (draft) angles, and a large envelope of excess metal around the part to be produced. These geometric features facilitate metal flow into the die cavities, and assure easy removal of the forged part from the dies. Considerable machining is required (as much as 90% of the material volume is removed) to obtain the final part shape and dimensions. Conventional and high definition forgings have progressively smaller machining envelopes,

Fig. 1 Blocker forging

smaller draft angles, and smaller radii, but still require machining all over to reach the final part shape. *Precision* forging, Fig. 2, on the other hand, uses segmented tooling in a trap die concept to form the part to net, or near-net, shape requiring little or no machining. Little if any draft angles are used because the die segments separate readily from the part.

Frequently, blocker forgings are used as preforms for conventional, high definition, and precision forgings. This distributes the billet material into a shape for easier flow in the more detailed die, but at the expensive of an additional die set and process step. Open die forging methods, such as fullering, gathering, and edging, are also used to redistribute material from a simple billet or bar shape into a preform that facilitates forging of the final shape without defects.

Impression forging dies are placed in a hydraulic press, mechanical press, screw press, or forging hammer (in order of increasing forging speed, respectively) which moves the dies together and applies force to the billet. These forces compress the material between the dies, forcing the material to deform plastically and flow into the recesses of the die, Fig. 3a. During forging, the material flows laterally, upward and/or downward into ribs and bosses, and then through a flash land. A flash gutter, Fig. 3b is provided around the periphery of the part impression to allow for the escape of excess metal and to produce back pressure that helps force metal into the die details. The flash is then trimmed off to give the final forged shape. The plane between the closed dies along which the flash forms

Fig. 2 Precision forging

is called the parting line; location of the parting line is an important design parameter since it affects the metal flow and pattern of microstructure in the part.

Billets for forging have a fiber, or grain flow pattern, along the axial direction due to elongation of inclusions and second phase particles during hot working by rolling or extrusion. Subsequent forging deformation realigns this fiber structure along the longitudinal dimensions of the die cavities (ribs and webs) of the forging, as shown

Fig. 3 (a) Metal flow and formation of flash in a conventional flash gutter in impression dies; (b) Flash details; (c) Section of a forging showing grain flow in the directions of metal flow; (d) Exposure of grain flow to the sheared surface by flash removal along the parting line

in Fig. 3c. These inclusions and second phase particles have a strengthening effect in the same way that fibers and particulate in metal matrix composites reinforce the material in the direction of their alignment. As a result, the strength of material in the length direction of ribs and webs is greater than the strength transverse to the ribs. Similarly, the flow of metal around the corner radii of the die (fillet radii in the part) strengthens the corner regions of the part. Through proper design, grain flow can be oriented along the directions that will experience the greatest stress in the part during use.

Unfortunately, grain flow also occurs as material flows into the flash, Fig. 3c, and trimming the flash may expose a plane of weakness in the material caused by the tight packing of inclusions and second phases within the narrow gap of the flash land. This plane of weakness around the periphery of the part may be a source of cracking if significant residual stresses are generated during subsequent heat treatment. Corrosion may also start along this plane of weakness when the part is placed in service or storage. Therefore, the parting line, and flash land, should not be located so that the exposed plane of weakness will be in a critical stress bearing location of the part, as in Fig. 3d.

In contrast to impression die forging, precision forging uses a trap die tool set made of die segments assembled within a yoke or die holder, Figs. 4 and 5, to produce a forging that is very close to the finished part shape and dimensions. Material flows along the web and into the ribs, as in impression die forging, but any excess material flows into thin flash zones at the top and bottom of the ribs, Fig. 2, rather than along the vertical surfaces, Fig. 1. Not only is the flash much smaller in precision forging, but any plane of weakness is at the tips of the ribs, rather than along the side of the part, and has little effect on material integrity.

Figure 4 shows a “through die” precision forging tool set. Note that the forged part is trapped within upper and lower punches and the die sidewall. The upper and lower punches form the part details and the die wall forms the outer vertical surfaces. The lower punch also serves to eject the forged part from the die. For more complicated shapes, a “wrap die” concept, Fig. 5, is used in which the die wall segments rotate outward as the part and die set are pushed upward out of the yoke after forging, or the die segments can easily be removed by hand from the forged part. This approach enables easy removal of the part from the die, which in turn eliminates the need for draft angles on the vertical surfaces. In addition, the wrap die concept allows for production of parts with undercuts, such as Fig. 6.^[1,2]

Clearly the tooling cost for blocker-type impression die forging is less (by a factor of three to five) than the cost for segmented precision forging dies. This cost can be offset by the reduced cost of machining for precision forgings, making precision forging economical for large quantities by amortizing the tooling cost.

2.2 Materials

Aluminum forgings are most commonly made of the heat treatable alloys, 2000, 6000, and 7000 series, whose composition and in-use heat treated properties are described elsewhere in this volume. For analysis of forging these alloys, however, we need to understand their mechanical properties at the temperatures and strain rates occurring in forging processes. Such data can be obtained in specialized test facilities that control the deformation stroke to give the desired strain rate, and provide a controlled heating environment around the test specimen to give the desired temperature uniformly throughout the specimen.^[3] Compression testing with low friction is normally used in this type of equipment to determine flow stress curves. Compression testing with friction, as well as bend tests, are used to determine the fracture behavior.

Flow stress curves for three examples of these alloy series, AA 6061, AA 2014, and AA 7075, are shown in Figs. 7–12.^[4] This reference also provides as-formed microstructures, and the flow stress data can be downloaded over the Internet for use in finite element models. Figures 7–9 show the significant effect of temperature on the flow stress; decreasing the forging temperature by 100°C more than doubles the flow stress, while increasing the forging temperature by 100°C decreases the flow stress by approximately one-half. Therefore, selection of the forging temperature has a critical effect on the ease of flow of materials, and the resulting precision and detail that can be formed in the forged part. The use of high preheat temperatures for forging, however, risks the development of

Fig. 7 Flow stress curves

Fig. 8 Flow stress curves

Fig. 9 Flow stress curves

hot shortness (severe cracking) due to incipient melting. The temperature rise due to deformation heating added to the billet preheat temperature may reach the solidus and melt low temperature phases in the material. This possibility is greatest in mechanical and hammer forging because the heat generated by deformation has little time to dissipate, essentially giving rise to adiabatic heating.

The flow stress of aluminum alloys is also affected significantly by strain rate, as shown in Figs. 10–12. At the

**Fig. 10** Flow stress curves**Fig. 11** Flow stress curves**Fig. 12** Flow stress curves

typical forging temperature of 350°C, increasing the strain rate from 0.1 per sec to 20 per sec increases the flow stress by one-half, while decreasing the strain rate to 0.001 per sec approximately halves the flow stress. A strain rate of 0.1 per sec is typical of hydraulic presses while the strain rate of 20 per sec is typical of mechanical presses, and the strain rate of 0.001 per sec occurs during creep forming. The low flow stress at the strain rates of hydraulic pressing enables finer details in forged parts than can be obtained in mechanical presses or hammers.

Since the forging temperature for aluminum alloys is relatively low, dies for forging aluminum (typically, a hot working grade of tool steel is used) can be heated to the forging temperature without seriously deteriorating then die material or die surfaces. This factor further facilitates metal flow by eliminating cooling of the workpiece, so that fine detail can be developed in the forging, particularly in hydraulic presses.

Generally, the conventional alloys described above are very ductile at the forging temperatures and do not crack, even under large deformations, during forging. The advanced alloys, e.g. aluminum-lithium alloys, metal matrix composites, and consolidated rapidly solidified powders, however, may have limited ductility at forging temperatures, even though their flow stresses are similar to the conventional alloys. To evaluate the ductility of the advanced alloys for forging applications, a workability test has been used, as shown in Fig. 13. Compression of cylindrical specimens of the material generates circumferential tensile stresses and axial compressive stresses, Fig. 13a, similar to those occurring in localized regions of a forging. Measurement of the surface strains during compression testing, Fig. 13b, leads to a workability diagram for the material, such as Fig. 13c, which can be used to determine the likelihood of cracking during an actual forging. This workability approach can also be used to evaluate changes in process parameters to prevent cracking.^[5]

Deformation Process Mechanics

Figure 14 shows again the two extremes in producing the same part by forging: a blocker-type forging in Fig. 14a, which has relatively large web and rib dimensions, draft angles, and radii, and requires considerable machining of material to reach the final required dimensions (shown by the dotted lines); and Fig. 14b, which shows a precision forging approach to the same part, with little or no machining required to reach the final dimensions. The forging loads and tool design for these cases are considerably different. The forging load for precision forgings is higher than blocker forgings, and the cost of tooling for precision forged parts is considerably higher than blocker forged parts.

To understand these differences and their implications for design with forgings, we will consider the mechanics of metal flow in the rib-web type aluminum forgings shown in Fig. 14. A wide variety of shapes can be produced by

forging, but the geometric features of this type of forging are representative, and will illustrate the main features of metal flow and pressures during forging. The slab method of analysis will be used; although it involves several approximations, it provides physical insight to the forging process and involves only simple calculations. This method of analysis is described in several references.^[6-8]

Generally, the forging billet is first contacted by the web sections of the die. As the billet undergoes compression, material flows laterally then vertically into the ribs. We will examine metal flow in the web and ribs separately, and then combine the results. The total load is made up of the pressure to form the web plus the pressure to form the ribs.

First, focusing on the lateral flow of metal in the web section, Fig. 15a, we can consider the behavior of a typical vertical element of material having height t (the web thickness) and width dx as it moves to the right (positive x -direction) with the metal flow. Vertical pressure p acts on the element as the upper and lower dies press on the billet. Since the element is moving to the right, away from the centerline, friction at the die contact surfaces will act to the left on the element, opposing the relative motion. In metal-working processes, friction is most accurately represented as $f = mk$, where k is the shear yield strength of the workpiece material, and m is a friction factor that ranges from 0.0 for perfect lubrication to 1.0 for perfect sticking of the workpiece material to the die. The shear yield strength k is equal to $0.577 S$, where S is the flow stress of the material.^[6]

With the friction forces acting to the left on the top and bottom surfaces of the element shown in Fig. 15a, there must be an internal horizontal force acting to the right on the element to maintain equilibrium. (Even though the element is moving, its acceleration is negligible, so static equilibrium is maintained, i.e., the sum of the forces in the x -direction equals zero.) An internal pressure, designated q , acts in the x -direction on the vertical faces, differing by a differential amount dq on each side of the element.

Applying horizontal equilibrium to the element,

$$\begin{aligned} qt - (q + dq)t - 2mk dx &= 0 \\ t dq - 2mk dx &= 0 \\ dq &= -2mk / t dx \end{aligned} \quad (1)$$

As the billet spreads to the edges of the web section of the die, the ends are free from stress, so $q = 0$ at $x = L/2$. Applying this boundary condition to Eq. 1,

$$\begin{aligned} q - 0 &= -(2mk/t)(x - L/2) \\ \text{or} \\ q &= mk(L/t)(1 - 2x/L) \end{aligned} \quad (2)$$

This distribution of internal pressure q , shown in Fig. 15b, has a peak value at the centerline and is symmetric about $x = 0$ because material to the left of the centerline flows to the left, and is a mirror image of the element shown in Fig. 15a.

(a)

(b)

(c)

Fig. 13 Workability testing: (a) upset test; (b) strains on the surface of the test specimen; (c) strains at fracture for AA 2024 at room temperature and hot working temperature

Since the element of material in Fig. 15a is undergoing plastic deformation, the stresses acting on the element must satisfy the yield criterion,^[6]

$$p - q = 1.15 S = 2k$$

where S is the flow stress of the material. Then the pressure on the die in the web region is

$$p = 1.15 S + q = 1.15 S \left[1 + (m/2)(L/t)(1 - 2x/L) \right] \quad (3)$$

which is also plotted in Fig. 15b. The peak pressure at the centerline is $1.155S [1 + (m/2)(L/t)]$.

Even though the web is flat and the compressive deformation is the same at any point along the web, the pressure distribution acting between the die and material is actually non-uniform, reaching a peak value at the center. Note

Fig. 14 Blocker (a) and precision forging (b)

Fig. 15 (a) Element of material in the web section during forging; (b) Schematic pressure distributions in the web

that the pressure at any point along the web increases with increasing web length to thickness ratio L/t , friction m , and flow stress S .

If we take $m = 0.3$, a typical value for aluminum forging, $L/t = 3$ for the blocker-type forging, and $S = 100$ MPa (approximately, for convenience) from Fig. 7 (AA 6061 at 350°C, 0.1 per sec strain rate), Eq. 3 gives the peak pressure in the web as 167 MPa. For a precision forging

having $L/t = 9$ (web thickness is one-third of the blocker web thickness), the peak pressure will be 270 MPa, or 60% higher than the blocker-type forging.

Figure 15 and Eq. 3 show that friction is the major constraint to metal flow in the web section, and its influence increases as the web thickness decreases. The effect of this frictional constraint can be reduced, to some extent, by tapering the web section, as shown in Fig. 16. Again examining a vertical element of material moving to the right in the web region, pressure from the die now has a component of force acting outward in the positive x -direction, counteracting the friction force acting inward. Equilibrium of the element in Fig. 16 gives

$$\begin{aligned} qt + p dt - 2mk dx - (q + dq)(t + dt) &= 0 \\ p dt - q dt - 2km dx - t dq &= 0 \\ dq &= [(p - q)dt - 2mk dx] / t \end{aligned}$$

If we again take $p - q = 2k = 1.15S$,

$$dq = 1.15S(dt/dx - m)dx/t \quad (4)$$

If the taper is represented by $t = T + (\tan A)x$, where T is the web thickness at the center ($x = 0$) and A is the taper angle, then $dt/dx = \tan A = A'$. Substituting these into Eq. 4.

$$dp = 1.15S(A' - m)dx / (T + A'x)$$

The boundary condition $q = 0$ at $x = L/2$ applies again, giving

$$q - 0 = 1.15S(A' - m)(1/A')[\ln(T + A'x)/\ln(T + A'L/2)]$$

$$q = 1.15S(m/A' - 1)\ln[(T + A'L/2)/(T + A'x)]$$

At $x = 0$, the horizontal pressure is

$$q = 1.15S(m/A' - 1)\ln[1 + (A'/2)(L/T)]$$

and the peak die pressure is $p = 1.15S + q$, or

$$p = 1.15S\{1 + (m/A' - 1)\ln[1 + (A'/2)(L/T)]\} \quad (5)$$

Fig. 16 Element of material in a tapered web section

Using Eq. 5, for a taper angle of 1° , and all other conditions remaining the same, the peak pressure for the blocker forging ($L/T = 3$) is 163 MPa, a reduction of only 2.4% compared to 167 MPa pressure for the flat web. A 3° taper angle reduces the peak pressure by 6.6%. However, for the precision forging ($L/T = 9$), Eq. 5 gives a peak pressure of 256 MPa for 1° taper, and 230 MPa for 3° degree taper, which are 5% and 15% less, respectively, than the 270 MPa pressure for a flat web.

Focusing now on the flow of metal into the ribs, the pressure required to force material into a rib cavity must overcome friction as well as the taper on the rib. Consider a horizontal element of material in the rib having width w and thickness dz , Fig. 17, as it moves upward (positive z -direction) with metal flow into the rib. Pressure p acts on each end of the element in contact with the die in the rib section. If there is no draft angle on the rib, the pressure p will act horizontally, but if the rib has a draft angle, a component of the pressure p will act downward in the vertical direction. Friction will also act downward on the ends of the element since the element is moving upward. Because of the friction forces and vertical components of the pressure from the die, the internal pressure q will differ by a differential amount dq on each side to maintain vertical equilibrium of the element. Applying equilibrium in the z -direction,

$$\begin{aligned} qw - (q + dq)(w + dw) + p dw - 2mk dz &= 0 \\ q dw - w dq + p dw - 2mk dz &= 0 \\ (p - q)dw - 2mk dz &= w dq \end{aligned}$$

Since the element is undergoing plastic deformation, the pressure difference must satisfy the yield criterion, $p - q = 2k = 1.15 S$, giving:

Fig. 17 Element of material in the rib during forging

$$dq = 1.15 S(dw/dz - 2m)dz/w \quad (6)$$

Also, the draft angle A on each side of the rib gives the variation of width of the element $w = W - 2(\tan A)z = W - 2A'z$, where W is the thickness of the rib at its base, $z = 0$.

Then Eq. 6 gives

$$dq = -1.15 S(2A' + m)dz/(W - 2A'z)$$

Since the pressure q is zero at the top of the rib, $z = h$, this boundary condition gives

$$q - 0 = -1.15 S(m/W)(z - h) \quad \text{for } A = 0$$

and

$$q - 0 = -1.15 S(2A' + m)/2A' \ln[(W - 2A'z)/(W - 2A'h)] \quad \text{for } A > 0$$

In final form,

$$q = 1.15 S m(h/W)(1 - z/h) \quad [A = 0]$$

and

$$q = 1.15 S(1 + m/2A') \ln \{ [1 - 2A'(h/W)(z/h)] / [1 - 2A'(h/W)] \} \quad \text{for } [A > 0]$$

The pressure distribution for this case, Fig. 18, shows a nearly linear decrease in q from the bottom to the top of the rib (linear decrease if the draft angle $A = 0$).

At the base of the rib, $z = 0$, the pressure required to fill the rib is

$$q = 1.15 S m(h/W) \quad [A = 0] \quad (7a)$$

and

$$q = 1.15 s(1 + m/2A') \ln[1 - 2A'(h/W)] \quad [A > 0] \quad (7b)$$

Taking $m = 0.3$ and a typical blocker-type forging rib, $h/W = 1.0$, Eqs. 7a and 7b give the following results for rib forming pressure for no draft and for draft angles of 1° , 3° and 5° :

$A(^{\circ})$	Rib Pressure (MPa) ($h = W$)
0	34.5
1	39.2
3	49.1
5	59.9

For a precision forging, with $h/W = 3$, and all other conditions remaining the same, the rib forming pressure becomes

Fig. 18 Pressure distribution along the length of the rib

$A(^{\circ})$	Rib Pressure (MPa) ($h = 3W$)
0	103
1	121
3	167
5	213

Note that forming thinner ribs (decreasing W by a factor of 3) at least triples the rib forming pressure, and the multiplying factor increases with increasing draft angle. Also, use of a 5° draft angle rather than no draft angle approximately doubles the rib forming pressure. This is the opposite effect of the taper angle in the web, Eq. 5, where the pressure component due to the taper angle in the web counteracts the effect of friction, while in the rib the pressure component due to the taper angle augments the effect of friction.

As metal flows to the end of the rib, an additional pressure is required to completely fill the corner radii of the rib. Near the corners, a cylindrical state of stress occurs, Fig. 19, which can be treated by an equilibrium analysis similar to that for the rib and web. In this case, the

material has nearly filled the corner and the unfilled region is defined by an arc of radius R .

The equilibrium analysis examines a quarter circular arc element moving into the corner at a distance r from the corner. The element is acted on by pressure from the die surfaces perpendicular to the corner. Friction also acts on the ends of the element in the direction opposing flow into the corner. These forces lead to a differential in radial pressure dq across the thickness of the arc element.

Applying equilibrium in the radial direction (origin at the intersection of the rib end and side surfaces), pressure q acting over the quarter circle arc gives a total force of $qr\sqrt{2}$ acting at 45° between the two corner surfaces and away from the origin. The pressure $q + dq$ similarly gives a total force of $(q + dq)(r + dr)\sqrt{2}$ acting in the opposite direction. The pressure and friction forces act over the element thickness dr and their components in the 45° direction are $2(p + mk)\sqrt{2}$. The square root factors appear in all terms, canceling out, and leaving:

$$qr - (q + dq)(r + dr) + p dr + mk dr = 0$$

or

$$dq = [mk + (p - q)]dr / r$$

Again, from the yield criterion, $p - q = 1.15 S = 2k$, giving:

$$dp = 1.15 S(1 + m/2)dr / r$$

At $r = R$, the free surface radius, the radial pressure $q = 0$, then

$$q - 0 = 1.15 S(1 + m/2)(\ln r - \ln R)$$

or:

$$q = 1.15 S(1 + m/2)[\ln(r/R)] \quad (8)$$

Fig. 19 (a) An element of material flowing into a corner of the rib; (b) Transition from the corner cylindrical stress state to the rib linear slab stress state

As shown in Eq. 8, in the limit, the pressure required to form a corner of zero radius ($R=0$) is infinite. Even small corners will require very high pressures for complete filling.

Transition from the cylindrical pressure state in the corners to the linear slab stress state in the rib occurs in a transition zone, Fig. 19b, defined by $r = w'/2$, where w' is the width of the rib at the end. Then, to calculate the pressure required to fill a corner, take $r = w'/2$ in Eq. 8. Using $m = 0.3$, $S = 100$ MPa, $w' = 12$ mm, 12 mm, and a corner radius of 1.6 mm, the pressure required to fill the corner is 175 MPa. For a corner radius of 3.2 mm, the required pressure drops to 83 MPa. Note that the corner filling pressure is the same order of magnitude as the pressure required to fill the entire rib.

The pressures required to form the die corners, ribs, and webs are additive, as shown in Fig. 20. Starting with the pressure required to fill the corner, this serves as the boundary condition for pressure in the rib. That is, taking q_1 from Eq. 8 as the pressure needed to fill the corner, the pressure for forming the rib is q_1 plus the calculation for rib forming (Eq. 7), giving the total pressure q_2 at the base of the rib. Similarly, this pressure serves as the boundary condition for the pressure in the web. In this case, from Fig. 20, the transition around the die corner involves applying the yield criterion at the junction between the rib and web. That is, q_3 at the end of the web equals the pressure at the base of the rib, q_2 , plus $1.15 S$. Then the internal pressure distribution q in the web is given by Eq. 2 plus q_3 , and the pressure distribution on the die in the web region is given by Eq. 3, modified to include q_3 . The total peak die pressure on the web at $x=0$ (for the case of no draft angles) is then

Fig. 20 Accumulation of pressure: q_1 from corner filling, q_2 from rib forming, q_3 from the junction between the rib and web, and finally P due to lateral flow in the web

$$p = 1.15 S [1 + (m/2)(L/t) + m(h/w) + (1 + m/2) \ln(w'/2R)] \quad (9)$$

where the three non-unit terms in square brackets represent the contributions to pressure from the web, rib, and corner, respectively. The pressure on the die in the web region increases substantially as the die corner radii R at the top of the ribs decrease, as the rib height h increases and the rib thickness W decreases, as well as when the web thickness t , itself, decreases. Calculation of the total forging load can be obtained by integrating the pressure distribution on the web section and the cross-sections of the ribs. The effects of web and rib angles can be included by replacing $(m/2)(L/2)$ by $(m/A' - 1) \ln [1 + (A'/2)(L/T)]$ from Eq. 5 and replacing $m(h/W)$ by Eq. 7b.

Another important aspect of metal flow during aluminum forging requires a more localized view of metal flow around a corner of the die, such as the radius between the rib and the web. If the die corner radius is too small, metal flow around the corner separates from the die. When the material reaches the top of the rib, it folds over on itself and causes a lap, as described in the sequence of Fig. 21. This phenomenon occurs only for relatively thick ribs having sufficient space for the material to fold over. Thin ribs, as in precision forging, prevent this type of defect.

Very high shear stresses generated during flow around such corners may cause periodic cracking in the surface material as it is extruded into the rib region, as shown in Fig. 22. For the conventional heat treatable alloys such as the 2000, 6000, and 7000 series as well as aluminum-lithium and consolidated powders, such defects are not very likely. However, in the metal matrix composites and powder alloys, cracking of this form is very prevalent. Paradoxically, cracking around the fillet radii in these hard to

Fig. 21 Illustration of the influence of die corner radius on the formation of laps

Fig. 22 Fracture during rib-web forging of a hard to work alloy: (a) cracking at the top surface and at the corner radius; (b) strain state at the top of the rib; (c) strain and pressure at the corner radius

work alloys is less likely to occur in thin ribs than in thicker ribs because the higher pressure required to form thin ribs prevents the ductile fracture mechanism from occurring at the base of the rib. Cracking is also possible at the top of the rib in hard to form alloys, as shown in Fig. 22, because friction along the rib surfaces pulls tensile stresses on the top free surface.

Finally the influence of forging design on die stresses must be taken into account. For example, in a blocker-type forging, Fig. 14a, pressures from the workpiece acting on the rib surfaces of the die produce a wedge effect that tends to expand the rib thickness, causing tensile stress concentration at the top of the rib cavity. However, the large radii in a blocker-type die will minimize such stress concentrations. In contrast, high definition forgings and conventional forgings have thinner ribs, which lead to sharper radii at the top of the ribs; they also have larger pressures acting on the rib sections of the die, as described by Eq. 7. This combination of circumstances leads to high stresses in the die and a greater likelihood of cracks (or die checking) in the die corners, as shown in Fig. 23. Die cracking of this type does not exist in precision forging, Fig. 14b, because the die segments meet at the tops of the ribs to allow for a parting line and flash, so tensile stresses do not occur in the rib corners.

Die wear is an additional problem that is affected by forging design. Small fillet radii on the forged parts require small corner radii on the die, which are susceptible to high wear if they are in an area where high die pressures and high metal flow rates occur. The localized generation of heat due to high deformation is augmented by the generation of heat due to friction at the corner, which raises

the temperature of the die corner and further aggravates the conditions for wear. This set of circumstances is particularly apt to occur at the corner radius joining a web and rib, especially if the rib thickness is small. The major result of these effects is reduced die life and/or increasing frequency of die reconditioning to maintain the forging dimensions within tolerance.

Insight into metal flow, defects, pressures and die stresses during forging can also be obtained through modern, high speed computing using large deformation, non-linear finite element codes, such as ALPID, DEFORM, and ABAQUS. Figures 24 and 25 are examples of the deformation patterns predicted by such codes for a rib-web shape in precision forging and in impression die forging.^[9] Such simulations use extensive computer time and are primarily useful at the present time for troubleshooting specific design problems, rather than as a general forging design tool. As computer hardware advances continue and numerical methods further reduce computational time, it is expected that computer simulations will be used iteratively to optimize forging and die designs. In the meantime, simple analyses such as Eqs. 1–9, empirical workability approaches such as Ref. [5] and experience-based rules of thumb are used for forging design.

FORGED PART DESIGN

The quantitative and qualitative results given in the previous section control the design of parts for aluminum alloy forging. Specifically, taper (draft) angles, fillet and corner radii, rib heights, and rib and web thicknesses are

Fig. 23 Influence of die fillet radius on cracking of the die (die checking)

Fig. 24 Simulation of a rib web shape in precision forging

Fig. 25 Simulation of a rib-web shape in impression die forging

limited by the forging method, tooling concepts and cost constraints. In addition, selection of the forging orientation and parting line affect the grain flow, ease of forging, and cost.

Parting Line

The line of separation of the dies is called the parting line, Figs. 1, 2 and 3a, and establishing the location and shape of the parting line is the first step in forging design. The decisions on choosing the parting line are different for impression die forging and precision forging. Obviously, to separate impression dies and allow removal of the forged part, the forging can have no undercuts, such as in Fig. 6. For precision forging, the dies are made for easy removal of the part after the die segments are removed from the die holder or yoke, Figs. 4 and 5. In this case, the parting line will be vertical (Fig. 2).

In impression die forging, the parting line should encompass the largest cross-section of the part. Spreading metal laterally is easier than forcing material into tall ribs, as seen from Eqs. 4 and 7. The part shown in Fig. 26, then should be forged with the orientation shown on the left because the rib heights are lower and has the largest cross-section of the two options. If the forged part can be

designed with one side flat, as in Fig. 27, the parting line is at the top and die manufacture is simplified because only one impression die needs to be machined.

Parting line selection also affects the grain flow in the part. With the parting line at mid-height of a rib, Fig. 3d,

Fig. 26 This section should be forged with the orientation shown on the left

Fig. 27 Forging with one flat side

the grain flow exits into the flash along a vertical surface, and the plane of weakness may be in a critical area regarding the loads to be transmitted by the finished part. Thus, the parting line and flash should be located at the extreme ends of the ribs, i.e. at the junction with the web, or at the tips of the ribs. In precision forging, the vertical parting lines, Fig. 2, assure that the flash always exits the tips of the ribs, causing no plane of weakness at a critical location.

Planes of symmetry allow easy centering of the part along the axis of force of the forging equipment, which avoids side thrust on the dies. If the forging equipment has sufficient capacity, a plane of symmetry can be enforced by forging two non-symmetric parts as one part with a common face acting as the plane of symmetry. Then the two parts can be separated by sawing or shearing operations.

Fillets and Corners

Sharp fillet radii in the parts (small corner radii in the dies) lead to a number of problems, including laps (Fig. 21), cracks (Fig. 22), and excessive die wear. The first two defects are avoided in precision die forging because the rib sections are thin, but at the sacrifice of the high cost of precision tooling. Suggested minimum fillet radii between webs and ribs for small rib heights on blocker-type

forgings is 0.50 in. and for precision forgings 0.125 in. For rib heights beyond 1 in., these part fillet radii should be increased by 0.50 in. for blockers and 0.125 in. for precision forgings, per inch of flange height. When forging hard to work alloys, these radii should be doubled.

Corner radii on forgings (fillet radii on the dies) should also be generous to allow for easy filling of the rib corners (Eq. 8) and to minimize stress concentrations at the fillet radii of the die during forging, shown in Fig. 23. Suggested corner radii are given in Fig. 28 for impression dies. The suggested minimum radius is 1/16 in. for small distances from the parting line, and then increases linearly with increasing height.

Web Thickness

As shown by Eq. 9, thin webs and ribs cause the forging pressure to become very large. If the maximum forging pressure on the die is taken as 1400 MPa, a typical limit for hot working die steels, the limiting part dimensions can be estimated from Eq. 9. Figure 29 shows a nomogram for such limits in the form of web thickness versus plan area of the forging. As shown in Fig. 16 and Eq. 5, supplying a taper on the web, Fig. 30, reduces the peak forging pressure and facilitates metal flow from the web to the ribs.

Fig. 28 Recommended corner radius limits for aluminum alloy forgings

Fig. 29 Nomogram for web thickness limits

Fig. 30 Tapered web facilitates metal flow to the ribs and reduces the forging pressure

Fig. 31 Example comparison of forging costs as a function of number of parts

Rib Height

As shown in Fig. 17 and Eq. 7, long, thin ribs require considerable forming pressure. Typically, the rib height-to-width ratio limits for blocker-type forgings is 5, for conventional forgings the limit is 15, and for precision forging the limit is 23. Draft angles are typically 10°, 3° and 1°, respectively.

Cost

For rib-web type forgings typically used in airframe structures, the total cost per piece for blocker-type forgings, conventional forgings, and precision forgings are shown in Fig. 31. With precision forgings, while the tooling cost is high the per piece cost drops rapidly with increasing production quantity because the tooling cost is amortized over each part and little machining is required. With blocker-type forgings although the initial tooling cost is low, machining cost remains high. Conventional forgings are an alternative for small quantities; typically between 50 and 100 production quantity, a crossover occurs whereby precision forgings become cheaper than conventional forgings on a per part basis. Of course, precision forgings are primarily carried out on hydraulic presses where the production rate is, at best, tens per hour so precision forging is applicable primarily for parts requiring limited annual quantities. Mechanical presses, on the other hand, which are capable of production on the order of thousands per hour, are necessary if large annual quantities are required. In this case precision forging to net shape without

machining is not feasible. Therefore, the tooling approach and tooling costs will vary depending on the quantity of parts required as well as the dimensional tolerances and dimensions required.

Designing with Aluminum Alloys

Nack J. Kim

Pohang University of Science and Technology, Pohang, Korea

Abstract

This article provides an overview of designing with aluminum alloys. Specific topics included in this review include: alloy designations, heat treatment of aluminum alloys, strengthening mechanisms, properties of aluminum alloys, Al-Li alloys, powder metallurgy of aluminum alloys, cast aluminum alloys, and temper designations. In addition, many reference tables are provided.

Keywords: Ageing; Alloy designations; Hardening; Heat treatment; Precipitation.

Since the discovery of age-hardening capability of Al-Cu alloys by Wilm in 1906, aluminum alloys have become important structural materials especially for aircraft and aerospace vehicles. This has been due to characteristics such as light weight, good corrosion resistance, good strength and ductility, to name a few. It also has good electrical and thermal conductivities. Aluminum can be cast and worked into almost any form and can be given a wide variety of surface finishes. It is anticipated that the importance of aluminum alloys will grow due to increasing demands on the energy conservation and environment a protection.

ALLOYING OF ALUMINUM

Pure aluminum has very low strength and cannot be used for structural applications when alloyed with other elements, however, it gains strength by various strengthening mechanisms. Aluminum can be alloyed with most metallic elements, but only some have enough solid solubility to be used as major alloying elements. Of more importance are copper, magnesium, silicon, and zinc (Table 1). However, a considerable number of other elements have pronounced effect on improving the properties of aluminum alloys. These include chromium, manganese, and zirconium, which are used primarily to control grain structure. Maximum solid solubility in aluminum alloys usually occurs at eutectic, peritectic, or monotectic temperature. Solid solubility decreases with decreasing temperature. Such change of solid solubility with temperature is the basis of age hardening (“Aging Treatment” section).

Alloy Designations

Wrought Alloys

There are various systems describing the compositions and temper conditions of wrought aluminum alloys. Among

these systems, the International Alloy Designation System (IADS) is widely accepted by most countries and it is used to describe alloys in this book.

Alloy is identified by a four-digit number in IADS. The first digit indicates the alloy group on the basis of major alloying element(s) as shown in Table 2. The second digit indicates alloy modifications. The original alloy is indicated when the second digit is 0. Other integers indicate alloy modifications. Therefore, the alloys with the same four-digit number except the second digit usually have similarity in composition. The last two digits are used to identify different aluminum alloys in the group and have no other special meaning. The only exception is the 1XXX group, where the last two digits designate the minimum percent of aluminum in excess of 99.00. A prefix X is used to denote an alloy, which is still considered experimental.

Casting Alloys

Aluminum casting alloys are usually identified by the three-digit registration system of the Aluminum Association. The first digit indicates the alloy group on the basis of major alloying element(s) as shown in Table 3. No commercial alloys are currently available in the 6XX and 9XX series. The second two digits have different meanings depending on the alloy systems. In the 1XX group, the second two digits indicate the minimum percentage of aluminum, e.g., 150 indicates a composition containing a minimum of 99.50% aluminum. In the 2XX–9XX alloy groups, the second two digits are used to identify different aluminum alloys in the group and have no special meaning. Aluminum casting alloys are often represented by the four-digit system, with the last digit at the right of the decimal point. This last digit indicates the product form, 0 being castings and 1 and 2 being ingots.

Table 1 Invariant reactions and maximum solubilities in binary aluminum alloys

Elements	Temperature ^a (°C)	Liquid solubility		Solid solubility	
		wt%	at. %	wt%	at. %

Prefix letter is also included when there is a modification to an original alloy, or to the normal impurity limits. X is assigned for experimental alloys.

HEAT TREATMENT OF ALUMINUM ALLOYS

Homogenization

The initial thermal treatment applied to ingots prior to secondary operation such as hot working is homogenization. Homogenization has one or more purposes depending on the alloy and product. One of the main purposes of homogenization is to reduce the effects of harmful microstructural features existing in cast structures. The cast structure is a cored dendritic structure with solute content increasing from center to edge with an inter dendritic distribution of second phase particles or eutectic. Since homogenization involves diffusion of alloying elements, the time required depends on the grain size or dendrite arm spacing and the rates of diffusion of the alloying elements. Solution of inter dendritic second phase particles also occurs during homogenization. However, in commercial high-strength aluminum alloys, it is not always possible to completely dissolve the inter-dendritic second phase particles. These are usually intermetallic compounds of the impurity elements, e.g., iron and silicon, with aluminum and/or the alloying elements. Therefore, it is necessary to minimize the size and number of these particles by reducing the iron and silicon content.

In other cases, homogenization is designed to induce formation of high temperature dispersoids in fine scale. Transition metals may supersaturate in aluminum during solidification. During homogenization, these elements form intermetallic compounds such as $\text{Al}_{20}\text{Cu}_2\text{Mn}_3$, $\text{Al}_{12}\text{Mg}_2\text{Cr}_3$, Al_6Mn , and Al_3Zr . These intermetallic compounds effectively control grain structure during subsequent fabrication and heat treatment by preventing recrystallization and / or grain growth. Homogenization temperature must be kept below the melting point of the constituent with the lowest melting point.

Solution Treatment

The main purpose of solution treatment is to obtain complete solution of most of the alloying elements for the subsequent aging treatment. Therefore, it should be carried out at a temperature within the single solid phase region. As in the case of homogenization, however, temperature must be limited to a safe level below the solidus temperature to avoid overheating and partial melting. It is especially true for the alloys with high solute content.

The grain size of hot- or cold-worked products can be significantly affected by solution treatment. Precautions should be taken in solution treatment of hot- or cold-worked products to prevent the growth of coarse,

recrystallized grains. Particularly with products that have varying amount of working at different locations, care should be taken not to have unnecessarily high temperatures and excessively long solution treatment times. Otherwise, the products would have a heterogeneous grain structure.

After solution treatment, aluminum alloy components must be fast cooled or quenched, usually to room temperature. The objective of quenching is to preserve the solid solution formed at the solution treatment temperature in preparation for subsequent aging. In general, the best combinations of strength and toughness are associated with the most rapid quenching rates. However, rapid quenching results in the distortion of thinner products such as sheet and the introduction of residual stresses into thicker products that are normally compressive at the surface and tensile in the core.

The effects of residual stress from quenching become serious when the products have an irregular shape or are machined. Machining disturbs the balance of the residual stresses, resulting in distortion of products. Also, the level of residual stresses may approach the yield stress in some high-strength alloys that can cause premature failure during service.

Several methods are available either to minimize the residual stresses generated during quenching or to relieve them after quenching. The most common methods used for stress relieving include stretching, roller leveling, and flattening in a press. The aging treatment also allows some relaxation of stresses. High residual stresses can be reduced by using slower cooling rates. This is particularly important for the irregularly shaped parts such as forging since the once formed residual stresses cannot be removed by subsequent working. Hence, the quenching of forgings is commonly conducted using hot or boiling water. In some cases, however, quench sensitive alloys may suffer a loss in mechanical properties when the slower quenching rates are used. Microstructural change which can occur by slow cooling is the precipitation of coarse particles which lowers the age-hardening response. Also, there can be a segregation of solutes such as copper to grain boundaries, which reduces toughness and increases the susceptibility to intergranular corrosion.

Aging Treatment

Aging treatment is the final stage in the development of properties in the heat-treatable aluminum alloys. Most of the heat-treatable alloys show age-hardening behavior at room temperature (natural aging) after quenching. But age hardening is greatly accentuated by heating at elevated temperatures (artificial aging), which are usually in the range of 100–190°C. The age-hardening behavior of aluminum alloys varies depending on the alloy compositions. Metallurgical changes that occur during aging are discussed below.

Precipitation

The decomposition process of the supersaturated solid solution (SSSS) is very complex and the resulting precipitation sequence varies depending on the respective alloy systems. Probable precipitation sequences in typical aluminum alloys are shown in Table 4. In general, Guinier–Preston (GP) zones and one or more metastable transition phases may be formed prior to the formation of equilibrium phase. GP zones are ordered, solute-rich clusters of atoms which are homogeneously nucleated in the matrix. They are about one or two atomic layers thick and fully coherent with the matrix. The equilibrium shape of a GP zone is a sphere such as those found in Al–Ag and Al–Zn systems (Fig. 1a). However, in Al–Cu system, GP zones have disc shape perpendicular to the elastically soft $\langle 100 \rangle$ directions in the aluminum matrix (Fig. 1b). This arises because the atomic size difference is large enough to make the strain energy more important in determining the equilibrium shape of the zone.

The formation of GP zones is usually followed by the precipitation of transition phases. The crystal structures of the transition phases are usually intermediate between those of the matrix and the equilibrium phase and are partially coherent with the matrix. For example, in Al–Cu system, there are two transition phases, θ and θ' (Fig. 2). θ has a tetragonal unit cell in which the copper and aluminum atoms are ordered on (0 0 1) planes. Since distortion in the [0 0 1] direction is very small, θ forms a fully coherent interface with the aluminum matrix. θ' is also tetragonal but has a large misfit in the [0 0 1] direction. Therefore, θ' is partially coherent with the aluminum matrix.

Nucleation of transition phases occurs at either the sites of GP zones or lattice defects, such as dislocations depending on the alloy systems. S (Al₂CuMg) and T₁ (Al₂CuLi) phases are typical examples of transition phases which precipitate heterogeneously on dislocations. Therefore, 2XXX alloys and Al–Li alloys are usually cold worked prior to aging to promote the formation of such phases

Table 4 Precipitation sequences in selected aluminum alloys

Alloy	Precipitation sequence
Al–Cu	GP (disc) → θ'' (disc) → θ' (plate) → θ (Al ₂ Cu)
Al–Mg	GP (sphere) → β' (plate) → β (Mg ₅ Al ₈)
Al–Cu–Mg	GP (rod) → S' (lath) → S (Al ₂ CuMg) (lath)
Al–Mg–Si	GP (rod) → β'' (needle) → β' (rod) → β (Mg ₂ Si) (plate)
Al–Zn–Mg	GP (sphere) → η' (sphere or plate) → η (MgZn ₂) GP → T' → T
Al–Li–Mg	δ' → Al ₂ LiMg (rod)
Al–Li–Cu	δ' → δ T ₁ (plate) θ'' → θ'

Fig. 1 Morphologies of GP zones; (a) spherical shape (Al-Mg alloy), and (b) disc shape (Al-Cu alloy). (Courtesy of J.K. Oh.)

Fig. 2 Transition phases in Al-Cu alloy; (a) θ'' , and (b) θ' . (Courtesy of J.K. Oh.)

Fig. 3 Precipitate-free zones; (a) formed by the depletion of solute atoms around coarse grain boundary precipitates (courtesy of J.K. Oh), and (b) formed by the depletion of vacancies near grain boundaries

in the microstructure. Maximum hardness occurs when a critical combination of coherent and semi-coherent particles is present. Formation of the equilibrium phase occurs with complete loss of coherency with the aluminum matrix and appreciable coarsening.

Precipitate-Free Zones at Grain Boundaries

It is a well-known fact that the grain boundaries are the main sinks for excess vacancies and solute atoms. This has important effects on the distribution of precipitates that form in the vicinity of grain boundaries upon subsequent aging. Nucleation and growth of precipitates at grain boundary deplete the solute near the grain boundary and a precipitate-free zone (PFZ) results upon aging as shown

in Fig. 3a. Also, since the vacancy concentration near the grain boundary is lower than that of the critical vacancy supersaturation required for the nucleation to occur, a PFZ is formed near the grain boundary upon aging (Fig. 3b). In this case, the width of the PFZ is determined by the vacancy concentration near the grain boundary, which is in turn controlled by heat-treatment conditions. High solution treatment temperatures and fast quench rates produce narrow PFZs by reducing the width of vacancy concentration profile. Low temperature aging also produces narrow PFZs since the driving force for precipitation is high and the critical vacancy supersaturation is low. Similar PFZs can form at dislocations and inclusions.

All age-hardenable aluminum alloys show PFZs along grain boundaries except when the alloys are aged at

temperatures below the GP zone solvus since GP zones can form homogeneously in some aluminum alloys. PFZs, in general, have a deleterious effect on the properties of aluminum alloys. Since they are softer than the surrounding matrix, the strain is localized along grain boundaries under applied stress and a premature failure can occur. It is also known that PFZs increase the susceptibility to stress-corrosion cracking.

PROPERTIES OF ALUMINUM ALLOYS

Hardening (Strengthening) Mechanisms

Precipitation and Dispersion Hardening

The strength of an age-hardenable alloy is controlled by the interaction between dislocations and precipitates. In general, an increase in strength is synonymous with an increased difficulty of moving dislocations. Either a dislocation must cut through the precipitate particles in its path, or it must move between them. In the early stage of aging, the precipitates are coherent with the matrix and can be sheared by dislocations. Shearing of precipitate particles increases the precipitate–matrix interfacial areas as shown in Fig. 4. High applied stress is needed for this to occur and the critical resolved shear stress is proportional to the precipitate particle size.

Although this so-called chemical strengthening significantly contributes to the strength of high-strength aluminum alloys, the shearing of precipitate particles may cause a degradation of other mechanical properties such as ductility and toughness. Once the precipitate particles are sheared, dislocations continue to pass through the precipitate particles on the sheared planes and hence deformation becomes localized on only a few slip planes developing intense slip bands as shown in Fig. 5. Such developed intense planar slip bands allow the pile-up of dislocations at grain boundaries, resulting in a premature failure along grain boundaries.

Fig. 4 Shearing of δ' precipitates by moving dislocations

Fig. 5 Occurrence of planar slip in Al-Li alloys due to the shearing of δ' precipitates

As the precipitate particles grow in size, they lose their coherency with the matrix and would not be sheared by dislocations. In this case, the precipitate particles are by-passed by moving dislocations which bow out between them (Fig. 6). Rejoining of dislocations results in the formation of loops of dislocations around precipitate particles. Strength is then inversely proportional to the distance between precipitate particles. This so-called Orowan mechanism is operative in overaged alloys and other dispersion strengthened alloys. The maximum strength is usually observed at the transition point when deformation behavior changes from shearing to by-passing of precipitate particles. The yield strength of the alloy is low but the rate of work hardening is high, and plastic deformation tends to be spread more uniformly throughout the grains.

Work Hardening

Work, or strain hardening, is a natural consequence of most working and forming operations and is used extensively to increase the strength of the non-heat-treatable aluminum

Fig. 6 By-passing of dislocations around shear-resistant dispersoids

alloys. For heat-treatable aluminum alloys, work hardening may supplement the strength achieved by precipitation hardening. Work-hardened products can be restored to a fully soft, ductile condition by annealing.

During deformation, the dislocation content increases when dislocation generation and multiplication occur faster than annihilation by dynamic recovery. Dislocation tangles, cells, and subgrain walls are formed, all of which decrease the mean free slip distance and increase the strength.

Usually, there is an initial rapid increase in yield strength of non-heat-treatable alloys by cold working, after which the increase is more gradual and roughly equals the change in tensile strength. The heat-treatable alloys in both the annealed and T4 temper conditions show a similar behavior. The work-hardened alloys, however, have much reduced ductility and formability as compared to the non-work-hardened alloys. Exceptions are 3003 and 3004 alloys, which exhibit better drawing properties in the cold worked rather than in the annealed condition. Good drawing properties of these alloys are obtained by the control of sheet texture by cold rolling and these alloys are used for making thin-walled beverage cans.

In the case of fully hardened heat-treatable alloys, the increase in strength by cold working after aging is comparatively small, except at very high strains, and is often limited by the poor workability of alloys in this condition. The principal use of this practice is for some extruded and drawn products such as wire, rod, and tube that are cold drawn after heat treatment to increase strength and improve surface finish.

The work-hardening characteristics of aluminum alloys vary considerably with temperature. Work hardening is much greater at cryogenic temperatures than at room temperature. The gain in strength by working at -196°C can be as much as 40% although there is a significant reduction in ductility. At elevated temperatures, the work-hardening characteristics vary both with temperature and strain rate. Work hardening decreases progressively as the working temperature increases until a temperature is reached above which no effective strain hardening occurs due to dynamic recovery and recrystallization. Dynamic recovery results in the formation of a subgrain structure that is similar to the structure resulting from heating a previously cold-worked alloy. Subgrain structure also increases the strength of aluminum alloys to some extent.

Textures

During hot or cold working, considerable numbers of the deformed grains approach certain orientations, forming crystallographic textures. Such texture occurs because deformation, or slip, in aluminum is confined to the $\{111\}$ planes in the $\langle 110 \rangle$ directions. Large amounts of deformation at ambient temperatures lead to some strengthening through the development of textures, the nature of which

depends in part on the mode of working. In rolled sheet, the deformation texture may be described as a mixture of the three ideal textures $(110)\langle \bar{1}12 \rangle$, $(112)\langle 11\bar{1} \rangle$ and $(123)\langle \bar{2}11 \rangle$. Wire, rod, and bar usually have a “fiber” texture in which the $\langle 110 \rangle$ direction is parallel to the axis of the product, with a random orientation of crystal directions perpendicular to the axis.

When cold-worked aluminum alloys are recrystallized by annealing, new grains form with orientations that differ from the principal components of the above-described deformation texture. In rolled sheet, there is a strong tendency for the new grains to form with a cube plane $\{100\}$ parallel to the surface and a cube edge parallel to the rolling direction, i.e. $(100)[001]$ texture. The texture and final grain size in recrystallized products are determined by the amount of cold work, annealing conditions (i.e., rate of heating, annealing temperature and time), composition and the size and distribution of intermetallic compounds which tend to restrict grain growth.

A consequence of the textures, particularly deformation texture, is the production of some directionality in properties. Texture hardening causes moderate increases in both yield and tensile strength in the direction of working. Forming characteristics of sheet may also be improved through an increase in the R -value for sheet. However, the texture may present a problem for the formation of ears during deep drawing of sheet. Earing describes the phenomenon of small undulations that may appear on the top of drawn cups. Earing may be minimized by careful control of rolling and annealing schedules, e.g., a sheet is sometimes cross-rolled so that textures are less clearly defined.

Toughness

The application of high-strength aluminum alloys in the aerospace industry has resulted in increased performance in the areas of fracture and fatigue. Minimum fracture toughness requirements become more stringent and, in the high-strength alloys, it is necessary to place a ceiling on the level of yield strength that can be safely employed by the designer. It is generally understood that the fracture of brittle constituent particles or the decohesion at the particle / matrix interface is responsible for the reduction of fracture toughness of commercial aluminum alloys (Fig. 7). Consequently, the main approach to improve the toughness of high-strength aluminum alloys has been the control of the levels of the impurity elements such as iron and silicon. It has been shown that the reduction of the combined levels of these elements from 1.0% to 0.5% doubles the plane strain fracture toughness of some Al-Cu-Mg alloys. As a consequence of this, a range of high toughness versions of older alloy compositions is now in commercial use in which the levels of impurities have been reduced (Table 7).

The amount of the submicron dispersoid forming elements should be held to the minimum required for control

Fig. 7 Cleavage fracture of Fe containing intermetallic particles

of grain structure, other mechanical properties, or resistance to stress-corrosion cracking. It has been shown that the alloys containing zirconium are more resistant to fracture than those containing manganese or chromium since zirconium forms relatively small (~20 nm in diameter) Al_3Zr particles.

The effect of the fine precipitates developed by age hardening is more complex. Usually, toughness is greatest in the underaged condition and decreases as aging proceeds to peak strength. Toughness can increase or decrease as the alloys are overaged, depending on the microstructure. When the overaged microstructure of an alloy consists of coarse precipitate particles or PFZs along grain boundaries, the alloy fails by intergranular fracture having poor toughness (Fig. 8). Lithium containing alloys are the typical example. On the other hand, in other alloys,

Fig. 8 Intergranular fracture caused by strain localization along grain boundaries (Al-Li alloy)

improvement in toughness may occur on overaging due to a reduction in yield strength.

Fatigue

To characterize the fatigue behavior of a material, the resistance to both initiation and growth of fatigue cracks must be evaluated. The resistance to fatigue crack initiation is expressed as a fatigue strength (stress) for a given number of cycle. Unlike steels, aluminum alloys do not exhibit the sharply defined fatigue limit in $S-N$ tests. When the fatigue crack growth (FCG) is of interest, the fatigue properties are expressed by the crack growth rate (da/dN) as a function of stress intensity range (ΔK). This type of FCG test is of prime importance for alloys used in aerospace applications.

It is generally known that improving the tensile strength increases the fatigue strength of aluminum alloys. However, the improvement in fatigue strength of aluminum alloys incurred by increase in tensile strength is lower than those of steels. The effects of large constituent particles and dispersoid particles on the fatigue strength of high-strength aluminum alloys are dependent on the type of fatigue test or stress regime chosen for evaluation. It has been shown that commercial-purity alloys have higher fatigue strength than equivalent high-purity compositions. The presence of inclusions and intermetallic compounds in commercial-purity alloys disperse slip during fatigue deformation, thereby delaying the crack initiation. However, the fatigue performance characteristics are reversed if FCG is measured. In this condition, the FCG is faster in the commercial-purity alloy because voids nucleate more readily at large constituent particles and dispersoid particles which are within the plastic zone of the advancing crack.

The effect of the fine precipitates developed by age hardening is also dependent on the type of fatigue test. During deformation of aluminum alloys, shearing of precipitates can occur resulting in a localization of strain in a limited number of slip bands. The occurrence of this so-called planar slip decreases the fatigue strength of aluminum alloys. On the other hand, the resistance to FCG can significantly be increased by the occurrence of planar slip. Planar slip results in a crack path along crystallographic planes and the resulting tortuous crack path induces crack closure effects associated with rough fracture surfaces and fretting debris (Fig. 9).

Corrosion

Aluminum alloys rapidly form a natural, protective film of alumina on their surface, making them quite corrosion resistant. Moreover, if the surface of aluminum is scratched sufficiently to remove the oxide film, a new film quickly re-forms in most environments. However, the oxide film can be dissolved in some chemicals, notably strong acids

Fig. 9 Tortuous fatigue crack path in 8090 Al-Li alloy. (Courtesy of C.S. Lee.)

and alkalis. When the film is removed, the metal corrodes rapidly by uniform dissolution.

The mechanism of the corrosion process is usually associated with a local cell action between the solid solution of the matrix and the intermetallic second phase with a different electrode potential. Therefore, the corrosion behavior of aluminum alloys is affected by their microstructure. For example, the susceptibility to localized corrosion or stress-corrosion cracking can be reduced by appropriate treatments such as T7X tempers for 7XXX alloys or T8X tempers for 2XXX alloys.

Corrosion resistance of aluminum alloys can be enhanced by the thickening of oxide films. This can be achieved by various chemical and electrochemical treatments such as conversion coating and anodizing. Both conversion and anodic coatings can be dyed to give attractive colors and the latter process is widely applied to architectural products. The use of Alclad products is another way to improve the corrosion resistance. The core alloy is cathodically protected by the cladding alloy due to their different corrosion potentials. The design of an aluminum structure can also have a large effect on its corrosion behavior. The design of joints and the presence of other metals are important factors.

WROUGHT ALUMINUM ALLOYS

Most of aluminum alloys are used for wrought products, e.g., rolled plate, foil, extrusions, tube, rod, bar, and wire. Working operations and thermal treatments transform the cast ingot structure into a wrought structure. Working characteristics and subsequently developed properties are greatly affected by the compositions of the alloys.

Temper Designations

In addition to the alloy designation mentioned in “Alloy Designations” section (Table 2), IADS has temper designation system to describe the thermal / mechanical history of alloys. Temper condition is identified by suffix letter and digits to the alloy number.

Basic Temper Designations

- F: As-fabricated.
- O: Annealed (wrought products only). Temper with the lowest strength and highest ductility.
- H: Cold worked (strain hardened).
- T: Heat treated to produce stable tempers other than F or O.

Strain Hardened Subdivisions

- H1: Strain hardened only. The degree of strain hardening is indicated by the second digit and varies with quarter hard (H12) to full hard (H18).
- H2: Strain hardened and partially annealed. Tempers ranging from quarter hard to full hard obtained by partial annealing of cold-worked materials with strengths initially greater than desired.
- H3: Strain hardened and stabilized. Tempers for age softening Al-Mg alloys that are strain hardened and heated at a low temperature to increase ductility and stabilize mechanical properties.

Heat-Treated Subdivisions

- T1: Naturally aged.
- T3: Solution treated, cold worked, and naturally aged to a substantially stable condition.
- T4: Solution treated and naturally aged to a substantially stable condition.
- T5: Cooled from an elevated temperature shaping process and then artificially aged.
- T6: Solution treated and then artificially aged.
- T7: Solution treated and stabilized.
- T8: Solution treated, cold worked, and then artificially aged.

Non-Heat-Treatable Alloys

Non-heat-treatable alloys include the various grades of pure aluminum and other alloys in which strength is developed largely by solid solution hardening and by strain hardening from the annealed temper. The major alloying elements include magnesium, manganese, and silicon. Chromium, copper, iron, and zinc are also added as minor elements (Table 5). It is worth mentioning that some of the above elements are often regarded as impurities in the other aluminum alloys. These elements form dispersoids with aluminum and other elements that provide dispersion

Table 5 Compositions of selected non-heat-treatable wrought aluminum alloys

strengthening. Non-heat-treatable alloys are in the 1XXX, 3XXX, 4XXX, and 5XXX series, with a few alloys in the 7XXX and 8XXX series. Typical mechanical properties of non-heat-treatable alloys are given in Table 6 along with their commercial forms and typical applications.

Pure Aluminum (1XXX Series)

There are various grades of aluminum: super-purity (SP) aluminum (99.99%) and commercial-purity (CP) aluminum containing up to 1% of impurities or minor additions. The structure of CP aluminum consists of small volume fraction of iron and / or silicon containing insoluble constituents in aluminum matrix. Strength of CP aluminum comes mostly from strain hardening. The maximum strength level occurs in alloy 1100, which is the “standard” CP aluminum alloy. Fully hardened alloy 1100 has a tensile strength of 165 MPa, with a yield strength of 150 MPa and an elongation of only 5%. Wrought products of CP aluminum are used in virtually all fields, with major consumption in the packaging, chemical, electrical, and architectural fields.

Al–Mn and Al–Mn–Mg Alloys (3XXX Series)

The only binary Al–Mn alloy of commercial interest is 3003. This alloy has about 1.2% manganese, which strengthened the aluminum by solid solution hardening and dispersion hardening of Al_6Mn particles. Addition of magnesium to Al–Mn alloy considerably improves the tensile properties by solid solution hardening. For example, alloy 3004 has a tensile strength of about 180 MPa in the annealed condition as compared to 110 MPa of alloy 3003. Manganese content in the 3XXX series of alloys is limited well below the maximum solid solubility. Iron as an impurity reduces the solubility and the coarse Al_6Mn particles may form with harmful effect on ductility.

Both alloys 3003 and 3004 have excellent corrosion resistance and moderate strength combined with high ductility. These alloys are used for general purposes where moderate strength and good weldability are required and find the applications previously mentioned for pure aluminum. In particular, alloy 3004 is mostly used for manufacturing beverage cans. Several lower strength alloys such as 3005 and 3105 have desirable combinations of strength,

formability, and corrosion resistance for applications in building and specialty products areas.

Al–Mg Alloys (5XXX Series)

The 5XXX series alloys contain about 0.8–5% magnesium as a major alloying element. Although magnesium has a greatly decreasing solid solubility with decreasing temperature in aluminum (Table 1), Al–Mg alloys do not show appreciable age hardening at concentrations less than 7% magnesium. However, magnesium provides substantial solid solution hardening and increases work-hardening capability. For example, the strength values of annealed Al–1Mg alloy are 40 MPa yield strength and 125 MPa tensile strength, which increase to 160 MPa yield strength and 310 MPa tensile strength by increasing magnesium content to 6%. Elongation over this range of magnesium is relatively high and exceeds 25%.

Alloys containing up to 3% magnesium are structurally stable at room and elevated temperatures, but structural instability may occur in alloys with higher magnesium content. The main cause of structural instability is the precipitation of β (Mg_2Al_3) phase, along grain boundaries or along slip bands. Although the precipitation of β

phase is slow at ambient temperatures, it is accelerated in the presence of severe strain hardening. Such structure is undesirable since it makes the alloys susceptible to intergranular attack and stress-corrosion cracking in corrosive conditions. Stress relieving at higher temperature (i.e., above solvus) is effective in preventing the formation of grain boundary precipitates, although it decreases the strength. Al–Mg alloys also have a tendency to soften with time (age softening) at ambient temperatures after strain hardening. Age softening occurs due to localized recovery within the deformed grains. This may be avoided by using H3 temper consisting of cold working to a level slightly greater than desired followed by stabilization at a temperature of 120–150°C.

Except a few general purpose commercial binary Al–Mg alloys, most of the 5XXX series alloys contain small additions of dispersion hardening elements such as chromium and manganese. These provide the increased tensile properties and raise the recrystallization temperatures.

Al–Mg alloys combine a wide range of strength, good forming, and welding characteristics, and high resistance to general corrosion. Probably, the most important property is the good welding response of the higher strength alloys under commercial welding processes. Weld strengths

equal the annealed strengths of the various alloys, and the welds exhibit good ductility. The high strength and good welding qualities make them widely used in transportation and structural fields including boats, truck bodies and large carriage tanks. Good low temperature properties also make them valuable in applications requiring good cryogenic properties.

Miscellaneous Alloys

This group covers a rather broad range of alloys which contain alloying elements not normally used in other series of aluminum alloys. Alloy 8001 containing nickel (1.1 wt%) and iron (0.6 wt%) has good resistance to corrosive attack in water at high temperatures and pressures and is used in nuclear energy applications. Its mechanical properties resemble those of 3003. Alloy 8011 (Al–0.75Fe–0.7Si) is used for bottle caps because of its good deep drawing qualities.

Tin containing alloys such as 8081 (Al–20Sn–1Cu) and 8280 (Al–6.2Sn–1Cu–1.5Si–0.45Ni) have excellent anti-friction properties, making them ideal for applications as bearings in automobiles. Alloy 8009 (Al–8.5Fe–1.3V–1.7Si) is a rapid solidification / powder metallurgy (RS / PM) processed alloy and contains iron in amounts much larger than its maximum solid solubility (0.05%). The alloy has good elevated temperature properties due to the presence of thermally stable $\text{Al}_{12}(\text{Fe,V})_3\text{Si}$ dispersoids (Fig. 10). General characteristics of PM alloys are described in “Powder Metallurgy Aluminum Alloys” section. One of the recently developed 6XXX alloys can be classified as non-heat treatable.

Heat-Treatable Alloys

Heat-treatable alloys develop their strength by age hardening and are one of the most important structural materials

Fig. 10 Fine dispersions of thermally stable $\text{Al}_{12}(\text{Fe,V})_3\text{Si}$ particles in RS / PM 8009 alloy

for aerospace applications. They are covered by the three series of alloys: 2XXX (Al–Cu, Al–Cu–Mg), 6XXX (Al–Mg–Si), and 7XXX (Al–Zn–Mg, Al–Zn–Mg–Cu). Lithium containing alloys are covered in separate section. They can be classified into two groups: those that have medium strength and are readily weld-able (Al–Mg–Si and Al–Zn–Mg), and the high-strength alloys that have been developed primarily for aircraft construction (Al–Cu, Al–Cu–Mg, and Al–Zn–Mg–Cu), most of which have very limited weldability. Compositions of representative commercial alloys are shown in Table 7. Typical mechanical properties are given in Table 8 along with their commercial forms and typical applications.

Al–Cu Alloys (2XXX Series)

The important wrought Al–Cu alloys are alloys 2011, 2025, and 2219. Alloy 2011 (Al–5.5Cu) contains small amounts of bismuth and lead that form discrete particles in the microstructure. It has good cutting characteristics and produces fine, easily broken chips during machining. Since

^aAlloys prepared by powder metallurgy techniques.

its introduction in 1934, it has been the basic aluminum screw-machine alloy. The bismuth and lead, however, lower the corrosion resistance of the Al–Cu alloys; hence, the T8 temper is used to obtain a higher resistance to corrosion for applications involving corrosive atmosphere.

Alloy 2025 (Al–4.5Cu) is the first Al–Cu alloy developed in North America and is still used extensively for forgings. But this alloy has been replaced in many applications by alloy 2219 (Al–6.3Cu), which has a more useful

combination of properties and is also available as sheets, plates, and extrusions. Alloy 2219 has a wide range of strength, good corrosion resistance and excellent elevated temperature properties. It also has good weld-ability and has been used for fuel tanks for storing liquefied gases such as hydrogen and oxygen that serve as propellants for missiles and space vehicles. Alloy 2219 is one of the alloys which show enhanced response to age hardening by strain hardening prior to artificial aging (T8 temper). Alloy 2219

in the T8 condition has yield strength more than 30% higher than in the T6 condition.

To meet requirements for increased tensile properties, several modified versions of 2219 have been developed. Alloy 2021 contains micro-addition of 0.15% cadmium and 0.05% tin, which refine the size of the semi-coherent γ precipitates during aging. It has a yield strength of 435 MPa, tensile strength of 505 MPa and elongation of 9% with no sacrifice of weldability or toughness at low temperatures. Another alloy is 2519 which contains a small amount of magnesium. One noticeable experimental alloy is the Al–6.3Cu–0.45Mg–0.3Ag–0.3Mn–0.15Zr. Additions of small amounts of silver and magnesium to Al–Cu alloy result in the precipitation of the Ω phase instead of the θ and θ' phases. Ω phase is very close to the equilibrium phase θ (Al_2Cu) that forms in binary Al–Cu alloys, but is quite stable at temperatures up to 200°C. In the T6 condition, the alloy has a yield stress as high as 520 MPa at room temperature, which compares with a typical value of 290 MPa for 2219. It also has superior creep properties to 2219.

Al–Cu–Mg Alloys (2XXX Series)

Al–Cu–Mg alloys have originated from the first precipitation hardenable alloy developed by Wilm in 1906. This alloy, called Duralumin (Al–3.5Cu–0.5Mg–0.5Mn), was used for the frames for Zeppelin airships. Alloy 2017 is a modified version of Duralumin and is now used mainly for rivets. Al–Cu–Mg alloys are now widely used for aircraft construction.

Alloy 2014 (Al–4.4Cu–0.5Mg–0.9Si–0.8Mn) contains silicon which make the alloy more responsive to artificial aging and therefore higher strengths than 2017. This alloy is used as forgings or extrusions for aircraft. Another alloy, 2024, in which the magnesium content is raised to 1.5% and the silicon content is reduced to impurity levels, has much enhanced response to hardening by natural aging at room temperature and is frequently used in T3 or T4 tempers. The strengthening phase in 2024 is S (Al_2CuMg) which preferentially nucleates on dislocations. Thus, a homogeneous distribution of dislocation produces a very fine and uniform distribution of S. Hence, the alloy

2024 has a high response to deformation prior to aging. The fuselage skin and the lower wing skins of most commercial passenger airplanes are made of 2024-T3 and it is used almost exclusively for the smaller general aviation aircraft. However, 2024 shows poor resistance to corrosion and stress-corrosion cracking so that its sheet and plate are normally roll-clad with pure aluminum or Al–1Zn.

In general, for equivalent yield strengths, the 2XXX series alloys have lower fracture toughness than the 7XXX series alloys (Al–Zn–Mg–Cu). This is mainly due to the larger sizes of intermetallic compounds in the 2XXX series alloys. Alloys 2124 and 2224 have been developed with reduced levels of iron and silicon impurities. They contain much reduced amounts of insoluble intermetallic compounds in the microstructure and have improved fracture toughness and ductility over 2024.

Although 2XXX series alloys have good combinations of mechanical properties which are needed for aircraft applications, they are prone to softening at around 120°C. Development of supersonic aircraft such as Concorde stimulated a need for a sheet alloy with improved creep strength on prolonged exposure at high temperatures. The alloy 2618 (Al–2.2Cu–1.5Mg–1Ni–1Fe) was developed to meet this need. In the alloy 2618, iron and nickel are important alloying elements, because they form Al_3FeNi phase which causes dispersion strengthening and assists in stabilizing the microstructure at elevated temperatures. Copper and magnesium contribute to strengthening through precipitation of S phase.

Lower strength Al–Cu–Mg alloys are being investigated as possible sheet materials for automotive applications. One example is 2036 which has nominal copper and magnesium content of 2.5% and 0.45%, respectively.

Al–Mg–Si Alloys (6XXX Series)

The 6XXX alloys contain additions of magnesium and silicon which, in the aged condition, precipitate Mg_2Si as a strengthening phase. In most cases, the magnesium and silicon are present in the alloy in amounts to nominally combine to Mg_2Si (Mg:Si 1.73:1). But silicon in excess of that needed to form Mg_2Si is also used. The excess silicon provides an appreciable increase in strength over that

obtained from a specific quantity of Mg_2Si by refining the size of the Mg_2Si particles and also precipitating as silicon. Manganese or chromium is added to most 6XXX series alloys because of their effects on promoting fine grain size and inhibiting recrystallization during solution treatment. The 6XXX alloys are widely used as medium-strength structural alloys which have the additional advantages of good weldability, corrosion resistance, and immunity to stress-corrosion cracking. The 6XXX alloys are used for the majority of extrusions, with smaller quantities being available as sheet and plate.

Alloy 6061 is the most well-known and widely used general purpose structural alloy in 6XXX series. It has a balanced composition of Al–1Mg–0.6Si (1.5% Mg_2Si) with 0.25% copper and 0.2% chromium. Copper is added to improve the strength and chromium is added to offset any adverse effect copper may have on corrosion resistance. Alloy 6053 is another alloy which has balanced composition (2% Mg_2Si). Moderate strength alloy 6063 was developed for the applications where strength requirement was less stringent. This alloy has about 1% Mg_2Si and can be readily extruded. The advantage of this alloy is that it can be quenched adequately during the extrusion operation as it comes from the press. Thus, a separate solution treatment is not needed. Alloy 6063 has excellent finishing qualities, ideal for application for architectural and decorative finishes. In alloy 6463, the iron content is kept to a low level (<0.15%) so that the alloy responds well to chemical brightening and anodizing for use as automotive trim.

Examples of the alloys which have excess silicon are the alloys 6066, 6070, 6151, and 6351. The presence of this excess silicon promotes an additional response to age hardening by both refining the size of the Mg_2Si particles and precipitating as silicon. However, these alloys have reduced elongation and toughness compared to the alloy 6061. The presence of chromium and / or manganese helps to counter this effect by promoting fine grain size and inhibiting recrystallization during solution treatment.

The alloy 6013 has a higher copper content than the other 6XXX alloys and is considerably stronger than 6061. It has excellent stretch forming characteristics and its properties in the T6 condition are comparable to 2024-T3, making it a potential replacement alloy for 2024-T3 sheet. However, alloy 6013 shows slight susceptibility to intergranular corrosion which is attributed to the presence of copper containing precipitates in grain boundaries.

Alloy 6262 contains lead and bismuth, which give the alloy improved machining characteristics. Alloy 6262-T9 has higher strength with somewhat lower machinability than the aluminum–copper alloy 2011. Alloy 6262 has much higher resistance to stress-corrosion cracking than 2011 and is preferred for more highly stressed fittings.

Recently, a new type of non-heat-treatable 6024 alloy has been developed which has all the characteristics of conventional heat-treatable 6XXX alloys. This alloy, having a nominal composition of Al–0.75Mg–1Si–1.4Mn–0.2Zr–0.3Cr,

has tensile properties equivalent to those of 6061-T6 in as-fabricated condition: a yield strength of 200 MPa, tensile strength of 350 MPa and elongation of 22%. A unique characteristic of this alloy comes from the presence of a rather large volume fraction of Al_6Mn dispersoids which provide dispersion strengthening. The alloy is subjected to faster solidification rate than normal to have a fine distribution of Al_6Mn dispersoids (Fig. 11). The size and distribution of Al_6Mn dispersoids are optimized during homogenization. Since aging treatment is not required for the alloy to obtain required properties, it is ideal for applications for long structural components of which the heat treatment is often not possible.

Al–Zn–Mg(–Cu) Alloys (7XXX Series)

These alloys have very pronounced age-hardening response and therefore have been the primary material for aircraft applications. 7XXX alloys mostly contain 4–8 wt% zinc and 1–3 wt% magnesium. Al–Zn–Mg alloys without copper have intermediate strength and are weldable. Copper additions of 1–2 wt% increase the strengths of Al–Zn–Mg alloys. 7XXX alloys are strengthened by the precipitation of GP zones and / or semi-coherent η' ($MgZn_2$) phase. One unique characteristic of the precipitation behavior of Al–Zn–Mg alloys is that η' precipitates can be nucleated from pre-existing GP zones. Also, deformation prior to aging has no effect on the precipitation behavior of these alloys. Copper additions do not change the basic precipitation mechanism of Al–Zn–Mg alloys. However, copper in GP zones increases its stability so that GP zones can exist at higher temperatures than in comparable Al–Zn–Mg alloys.

Although these alloys have excellent tensile properties and good fabricating characteristics, they have somewhat high susceptibility to stress-corrosion cracking. Improvements in resistance to stress-corrosion cracking have come by control of both compositions and heat-treatment procedures.

In general, overaging of 7XXX alloys results in a large decrease in tensile properties but with a significant increase in resistance to stress-corrosion cracking. The T73 temper

Fig. 11 Al_6Mn dispersoids in non-heat-treatable Al–0.75Mg–1Si–1.4Mn–0.2Zr–0.3Cr alloy. (Courtesy of S.W. Nam.)

was developed to improve the resistance to stress-corrosion cracking with a small sacrifice in tensile properties. The T73 temper is a duplex aging treatment consisting of the first aging step at low temperature (e.g. 120°C) followed by an overaging step at a higher temperature (160–170°C). A fine dispersion of the η' precipitates could be obtained through nucleation from pre-existing GP zones. Thick sections of 7075-T73 have high resistance to stress-corrosion cracking, albeit at the expense of strength. 7075-T73 is used for critical aircraft components such as very large die forging. Another duplex ageing treatment, designated T76, has been applied successfully to 7XXX alloys to increase resistance to exfoliation (layer) corrosion.

Aluminum alloys are usually cold water quenched to exploit their full potential for age hardening. However, it can introduce high levels of residual stress that contribute to stress-corrosion cracking. Using the slower quench rates (e.g. air cooling) from the solution treatment temperature minimizes residual stresses and decreases differences in electrode potentials throughout the microstructure, resulting in an improvement to resistance to stress-corrosion cracking. However, slow quench cannot be utilized to the chromium or manganese bearing alloys which have high quench sensitivity (“Solution Treatment” section). As a consequence, zirconium replaces chromium and manganese for the purpose of inhibiting recrystallization during solution treatment. Such alloys (e.g. 7010 and 7050) are not quench-sensitive and thus are used for thick sections in military aircrafts. 7050 also has somewhat higher copper content than 7075 in order to increase the strengthening associated with the second stage of the T73 treatment. The slightly modified version of 7050, 7150, is used as an improved performance upper wing skin alloy for several types of passenger aircrafts.

To combine the high strength of T6 with the resistance to stress-corrosion cracking equal to T73, another heat treatment has been developed. This is known as retrogression and re-aging (RRA) which involves the following stages for 7075: (1) conventional T6 treatment (solution treatment at 465°C, cold water quench, age 24 hr at 120°C), (2) short heat treatment (e.g. 5 min) at a temperature in the range 200–280°C and water quench, (3) re-aging at 120°C for 24 hr. The RRA treatment results in a microstructure having a matrix similar to that obtained for a T6 temper, combined with grain boundary regions characteristic of a T73 temper in that precipitates are larger and more widely separated. Reduced susceptibility to stress-corrosion cracking has been attributed to this latter change. However, the RRA treatment has been difficult to apply to thick sections because of the short time interval initially proposed for stage (2). More recently, the time and temperature conditions for this stage of the process have been optimized (e.g. 1 hr at 200°C) and the RRA treatment has been given the commercial temper designation T77. It has been applied to the new highly alloyed composition 7055 (Al–8Zn–2.05Mg–2.3Cu–0.16Zr) that has been used for structural

members of the wings of the new Boeing 777 passenger aircraft.

Other compositional changes have been made to improve the strength and toughness. One typical example is alloy 7475. 7475 has a much reduced level of iron and silicon impurities (combined maximum of 0.22%) compared to 7075 (0.90%) (Table 7). 7475 also has the manganese content reduced from 0.30% maximum to 0.06% maximum. Hence, the size and number of deleterious intermetallic compounds are much reduced in 7475, resulting in an improved fracture toughness over 7075 at same temper condition and tensile strength. This alloy is widely used in aircraft in the form of thick plate and forgings.

Compared to high-strength 7XXX alloys, medium-strength Al–Zn–Mg alloys have the advantage of being readily weldable. Unlike the other weldable aluminum alloys, these alloys age harden significantly at room temperature. Also, solution treatment temperature for the alloys can be as low as 350°C and the strength is relatively insensitive to cooling rates from high temperatures. Therefore, the alloys retain most of their strengths after welding. Most of these alloys contain smaller amounts (0.1–0.3%) of one or more of the elements chromium, manganese, and zirconium. These elements are added mainly to retain the dynamically recovered structure and prevent excess growth of recrystallized grains during fabrication. Weldable Al–Zn–Mg alloys find their applications in various areas including truck bodies, railroad cars, and portable lightweight military bridges.

Al–Li Alloys

Probably one of the most important aluminum alloys developed in the last decades is the Al–Li alloy. By adding lithium, a new class of aluminum alloys has been developed which offers significant weight savings over conventional aluminum alloys. Lithium decreases the density (3% for each 1% added) and increases the stiffness (6% for each 1% added) of aluminum. Al–Li alloys also have unusually high resistance to fatigue crack growth. Because of these unique features, some of Al–Li alloys have now attained commercial status for use in aircraft structures.

Age hardening of binary Al–Li alloys produces the precipitation of an ordered, metastable phase δ' (Al_3Li) that is coherent and has a particularly small misfit with the matrix. Small amounts of zirconium are also added in all variants of Al–Li alloys to control recrystallization and grain size. One other effect of this element is that nucleation of some of the δ' precipitates occurs on Al_3Zr dispersoids (see arrow, Fig. 12).

Due to the coherency, the δ' particles are sheared by moving dislocations giving rise to planar slip (Fig. 5). The resulting planar slip bands lead to strain localization at grain boundaries, giving rise to cracking along grain boundaries. Therefore, the aged binary Al–Li alloys suffer from low ductility and toughness and further alloying

Fig. 12 δ' precipitates in an Al-Li-Cu-Mg-Zr alloy. The arrows indicate Al_3Zr dispersoids. (Courtesy of C.S. Lee.)

elements are needed for the formation of additional precipitates to homogenize deformation and prevent strain localization.

The addition of copper leads to the enhanced precipitation of δ' and co-precipitation of θ' (Al_2Cu) and T_1 (Al_2CuLi) phases. T_1 precipitates are the predominant copper bearing strengthening precipitate in the commercial Al-Li-Cu alloys such as 2090. T_1 nucleates heterogeneously on dislocations and low angle boundaries so that 2090 is normally cold worked before aging (T8 temper) to promote a more uniform distribution. The presence of T_1 along grain boundaries mitigates strain localization. There can also be a formation of quasicrystalline T_2 (Al_6CuLi_3) phase. T_2 phase nucleates predominantly at high angle grain boundaries, reducing ductility and toughness.

Addition of manganese to binary Al-Li alloys results in the precipitation of the incoherent Al_2LiMg phase. However, this phase precipitates preferentially at grain boundaries and does not reduce planar slip behavior. It has an adverse effect on ductility, toughness, and corrosion behavior due to coarse grain boundary precipitates and associated PFZs. However, the addition of manganese to ternary Al-Li-Cu alloys introduces the co-precipitation of S' (Al_2CuMg) phase in addition to T_1 and δ phases. The S phase nucleates heterogeneously on matrix dislocations and low angle grain boundaries so that Al-Li-Cu-Mg alloys are normally cold worked prior to aging (T8 temper) to promote a more uniform distribution. S' phase forms as laths that are not readily sheared by dislocations, thereby promoting more homogeneous slip. The relative amounts of δ' , T_1 , and S' phases in Al-Li-Cu-Mg alloys depend on the relative concentrations of three alloying elements. High copper and lithium content relative to magnesium results in the dominant precipitation of T_1 phase. Preferential precipitation of S occurs when alloys have higher copper and magnesium content than lithium.

Another type of Al-Li alloy is available, which is weldable and has high strength at cryogenic temperatures.

This alloy, 2095, is based on Al-Li-Cu-Mg alloy and contains small amounts of silver. Addition of silver promotes the precipitation of a fine dispersion of T_1 phase along with S' and θ' in the peak aged condition. It has a minimum yield strength of around 600 MPa in T6 condition, which is double that of 2219-T6. It also maintains its high strength and high toughness at the cryogenic temperatures associated with storage of liquified gases. It is currently considered for applications for the welded fuel tanks of space vehicles in place of the existing alloys 2229 and 2014.

The original objective in developing the Al-Li alloys was as direct substitutes for conventional aircraft alloys. While a number of applications were pursued in aircraft and launch vehicles, these alloys had shortcomings that limited their applications. Alloys 2090, 8090, and 2091 have the solute content near the maximum that could be dissolved in solid solution, resulting in pronounced quench sensitivity. Except for thin gauges, embrittling equilibrium phases nucleated during quench and coarsened during aging. Moreover, prolonged exposure of stressed alloys to elevated temperatures ($> 50^\circ\text{C}$) can lead to relatively high rates of creep crack growth. Alloy 2297 (Al-2.8Cu-1.3Li-0.3Mn-0.1Zr) contains lower lithium content than the other Al-Li alloys and has a good combination of strength and toughness in all orientations, thermally stable properties and good corrosion resistance. This alloy is currently used as replacements for fighter aircraft structural parts which have limited fatigue life due to severe flight spectra loading.

Powder Metallurgy Aluminum Alloys

Conventional powder metallurgy (PM) processing of aluminum alloys involves the production of powders which are then cold pressed and sintered at elevated temperatures. Such processing has the advantage of near net shape production, thereby enabling the costs associated with machining to be minimized. But there are only a few aluminum alloys with moderate properties that permit a sintering despite the oxidation of powder surface. This has led to the development of several novel processes such as rapid solidification, spray forming, and mechanical alloying. These new processes have enabled new, and sometimes unconventional, alloys to be produced, thereby extending the range of properties available from powder compacts. They have certain advantages when compared to the ingot metallurgy processing, such as finer and more homogeneous micro-structure, extension of solid solubility, and formation of metastable phases, with the possibility of better mechanical properties and corrosion resistance.

Rapid solidification (RS) processing of aluminum alloys involves solidification at very high rate (up to $10^5^\circ\text{C}/\text{sec}$) from the melt to produce a powder or ribbon. Powders are produced by gas atomization in which molten alloy is sprayed through a nozzle into a stream of high velocity gas such as nitrogen or argon. Ribbons are made

by melt spinning in which the molten alloy is forced into an orifice onto a water-cooled rotating wheel. Ribbons are pulverized into flakes for subsequent consolidation. Mechanical alloying is a dry, high energy ball milling process that makes it possible to produce dispersions of oxides, carbides or nitrides in fine powders. Consolidation of powders or flakes is usually done by canning, degassing and hot pressing followed by extrusion or forging. Steps of canning, degassing, and hot pressing can be replaced by vacuum hot pressing. The major obstacle is the presence of oxide layers along the surface of powder particles, which may prevent inter-particle bonding during consolidation with consequent deleterious effect on mechanical properties (Fig. 13). Spray forming is basically the same as atomization; however, in this case, the resulting spray of droplets is deposited on a rotating collector plate to produce a compact perform. Preforms, which may be 98–99% of the theoretical density, can be extruded or forged to obtain a full density. The advantage of spray forming over atomization is that some of the steps involved in normal powder processing are eliminated. Also, particulates (e.g. SiC) may be injected into the gas stream to produce metal matrix composites directly.

Although the refinement of microstructure can be obtained by PM processing, the gain in mechanical properties by utilizing rapidly solidified powders without alloy modification is only marginal. The real advantage of PM processing is that novel alloys can be developed that cannot be fabricated by conventional ingot metallurgy. Alloying aluminum with oxygen, carbon, nitrogen, transition metals, rare earth metals, and lithium has been made.

Better combinations of strength and resistance to both corrosion and stress-corrosion cracking have been obtained by the additions of cobalt, zirconium or nickel to an Al–Zn–Mg–Cu alloy which produces a fine dispersion of the intermetallic phases in the PM product. Commercial alloys such as 7090 and 7091 (Table 7) are now available.

Iron, which is regarded as the most deleterious impurity in aluminum alloys, has been utilized for the development of PM aluminum alloys for elevated temperature

applications. There are several variants of these so-called high temperature aluminum alloys, including 8009 (Al–8.5Fe–2.4V–1.3Si) and 8019 (Al–8.3Fe–4.0Ce) alloys. Good elevated temperature properties of these alloys are achieved by the formation of a large volume fraction of thermally stable dispersoids. For 8009, additions of vanadium and silicon to Al–8.5Fe alloy result in the fine dispersion of thermally stable $\text{Al}_{12}(\text{Fe,V})_3\text{Si}$ dispersoids (Fig. 8). Sintered aluminum powders (SAP) were one of the first aluminum alloys which utilize oxide dispersion effect of mechanical alloying. SAP has superior creep resistance at temperatures above about 200–250°C compared to conventional aluminum alloys, but has insufficient strength at low temperatures. It is currently used for fuel element cans in nuclear fission reactors which use organic coolants.

Powder metallurgy processing has also been used for the development of several low density Al–Li alloys. These alloys incorporate higher lithium content than ingot alloys and this offers further potential for reducing density and increasing stiffness. The lithium content in these alloys is high, however, the amounts of copper and / or magnesium should be reduced so as not to exceed the solid solubility limit. Consequently, the alloys do not have enough amounts of T_1 and / or S' to disperse slip. The formation of a large volume fraction of Al_3Zr dispersoids, which is possible only via PM approach, has been shown to be quite effective in dispersing slip (Fig. 14).

Powder metallurgy techniques also enable the creation of materials with improved wear properties. An example is the hypereutectic Al–Si alloys and mechanical properties are again much greater than those of the equivalent conventionally cast alloy due mainly to the finer dispersion of the primary silicon phase (Fig. 15). Another example is Al–17Si–6Fe–(1–4.5)Cu–0.5Mg alloy which is currently used as piston materials of two-stroke snowmobile (Yamaha) and Lysholm compressor rotor (Mazda Motor Co., Ltd.).

Powder metallurgy has been successful in the development of new aluminum alloys that exhibit superior properties for certain applications. However, it is necessary

Fig. 13 Oxide layers along the prior powder particle boundaries of RS / PM Al–Li alloy

Fig. 14 Al_3Zr dispersoids in RS / PM Al–Li–Zr alloy

Fig. 15 Effect of solidification rate on refining the size of primary particles in hypereutectic Al-Si alloys; (a) ingot cast, and (b) spray cast. (Courtesy of W.J. Park.)

to appreciate that the PM alloys carry a significant cost premium so that potential applications are likely to be confined to specialized products, where an increased price is justified by the demand for improved properties.

CAST ALUMINUM ALLOYS

Aluminum alloys can be cast in virtually all molds, including sand molds, permanent molds, and high pressure dies. The aluminum melt can be fed either by gravity or by applying pressure. Solidification is much more rapid when the alloys are cast in metal molds and, therefore, a given alloy will be fine grained as a permanent mold casting. Aluminum alloys have several advantages for casting; relatively low melting temperatures, good fluidity, negligible solubility for all gases except hydrogen, and a good surface finish. However, aluminum castings have the problem of the relatively high level of shrinkage (3.5–8.5%) that occurs during solidification. Usually, the mold is designed to accommodate the occurrence of shrinkage and achieve dimensional accuracy. Selection of alloys for particular casting processes depends primarily on composition which, in turn, controls characteristics such as solidification range, fluidity, susceptibility to hot cracking, etc. Compositions of representative commercial alloys are shown in Table 9. Typical mechanical properties are given in Table 10 along with their typical applications.

Recently, several novel casting processes have been developed which offer several advantages over conventional casting processes; semi-solid processing and squeeze casting. In semi-solid processing, the dendrites are broken up by vigorously agitating the melt during solidification, increasing the fluidity. Each broken piece of dendrite

becomes a separate crystal and a very fine grain size can be achieved. Semi-solid processing has the advantage of much lower capital investment and operating costs when compared with conventional casting methods. Squeeze casting process involves compressing the liquid metal in a hydraulic press during solidification. The high pressure promotes intimate contact between casting and mold walls, resulting in an increase in solidification rate. Both semi-solid processing and squeeze casting can be used for the production of composite materials.

Temper Designations

The temper designations for castings are the same as those used for wrought products (“Temper Designations” section). However, this does not apply for ingots. As with wrought aluminum alloys, casting alloys include both heat-treatable and non-heat-treatable alloys. Non-heat-treatable alloys are usually used in as-cast condition, identified by a suffix F or by omission of any suffix. Solution treatment (T4 temper), however, is often applied to improve the ductility of some alloys such as aluminum–silicon alloys. Both heat-treatable and non-heat-treatable alloys may also be thermally stress relieved (O temper). For the heat-treatable alloys, the O, T4, T5, T6, and T7 tempers are normally applied to improve mechanical properties.

Pressure die castings are not normally solution treated since heating to the high temperature causes blistering due to the expansion of air entrapped during the casting process. Also, the distortion of castings may occur as residual stresses are relieved. However, recent improvements in die casting process have resulted in a quality which is compatible with solution treatment and have permitted the use of T6 and T7 tempers.

Table 9 Compositions of selected aluminum casting alloys

AA number	Casting process	Si	Fe	Cu	Mn	Mg	Cr	Ni	Zn	Ti	Other
150.1	Ingot	^a	^a	0.10					0.05

Al-Si Alloys

Aluminum casting alloys with silicon as the major alloying addition are the most important commercial casting alloys because of their superior casting characteristics imparted by the presence of relatively large volumes of the Al-Si eutectic. These alloys also have the advantage of high corrosion resistance, good weldability, and the low thermal expansion coefficient. Machining may present difficulties because of the presence of hard silicon particles in the microstructure. However, using tungsten carbide tools

with appropriate coolants and lubricants or polycrystalline diamond tools results in good quality machining.

Microstructure of binary Al-Si casting alloys is characterized by the presence of a eutectic, consisting of plates or needles of silicon in a continuous aluminum matrix. When slowly solidified, the structure becomes very coarse with large plates or needles of silicon. Alloys having this coarse eutectic exhibit low ductility because of the brittle nature of the large silicon plates. Fast cooling, as it occurs during permanent mold casting, greatly refines the microstructure and the silicon phase assumes a fibrous form with the result

that both ductility and tensile strength are much improved. Die casting produces an even faster rate of cooling with a much more refined microstructure. The eutectic may also be refined by alloy modification.

The modification of Al–Si alloys is commonly achieved by the addition of a small amount of sodium (0.001–0.003%), either as metallic sodium or as sodium salts before casting. It is usually necessary to add several times the amount of sodium required since sodium is lost continuously during holding of the melt. However, over modification promotes the formation of coarse silicon particles. Another problem involved with the modification by sodium is that the effects of modification are lost if Al–Si castings are re-melted which prevent foundries being supplied with pre-modified ingots.

Modification can also be achieved by the addition of other elements such as strontium or antimony. Although strontium is also lost during holding of the melt, its loss is much less and the degree of modification increases with holding time for several hours. The modified microstructure is retained after re-melting and the over modification is also less of a problem with strontium. Another advantage of strontium additions is that they suppress formation of primary silicon in hypereutectic alloys, resulting in improvements in ductility and toughness. Either Al–Sr or Al–Si–Sr master alloys can be used in adding strontium. Although the use of antimony has not been generally accepted as a result of hygiene and toxicological concerns, the effect of antimony on modification is essentially permanent in comparison with the transient effects of sodium or strontium.

Binary Al–Si alloys are used for sand and permanent mold castings for which strength is not a prime consideration. Alloy 443 (5.3% Si) may be used with all casting processes for parts in which good ductility, good corrosion resistance, and pressure tightness are important. Die cast alloy 413 (12% Si) has good corrosion resistance and has superior castability and pressure tightness compared to alloy 443. Alloy A444 (7% Si) has high ductility when cast in permanent mode and heat treated to T4 condition and is used when impact resistance is a prime consideration, e.g., domestic cookware, pump casings, and certain automobile castings, including water-cooled manifolds.

Strength of Al–Si alloys can be significantly increased by the addition of other alloying elements such as copper and magnesium. Copper increases strength and improves machinability, at the expense of reduced ductility and corrosion resistance. The higher silicon alloys are used for pressure die castings, whereas alloys with lower silicon and higher copper are used for sand and permanent mold castings. In general, Al–Si–Cu alloys are used for many of the applications listed for the binary alloys but where higher strength is needed. Many castings of Al–Si–Cu alloys are supplied only in the as-cast temper. However, the strength and machinability of some of these castings can be improved by T5 heat treatment. One example is the use

of alloy 319 (Al–6Si–3.5Cu) for die cast (permanent mold) automotive cylinder heads in place of cast iron. As with the wrought alloys, some compositions contain minor additions of elements such as bismuth and lead which improve machining characteristics.

Large quantities of sand and permanent mold castings are made from Al–Si–Mg alloys which are strengthened by the precipitation of Mg_2Si . Typical alloys are 356 (Al–7Si–0.3Mg) and 357 (Al–7Si–0.5Mg) alloys. These alloys have excellent casting characteristics, weldability, pressure tightness, and corrosion resistance. They are heat treatable to provide various combinations tensile and physical properties. These alloys find particular use for aircraft and automotive applications, one recent example being their increasing use for lighter-weight, cast motor car wheels. In some cases, the properties of these alloys are quite comparable to those of high-strength wrought alloys. This suggests that the possible replacement of some wrought components by these relatively cheaper castings may be a trend in the future.

Additions of both copper and magnesium to Al–Si alloys result in higher strength than the ternary alloys, with some sacrifice in ductility and corrosion resistance. One example is A390 (Al–17Si–4Cu–0.55Mg) which has been used for sand and permanent mold castings of all-aluminum alloy automotive cylinder blocks. The alloy has high wear resistance due to a large volume fraction of fine primary silicon particles. Refinement of primary silicon particles is achieved by the addition of 0.01–0.03% phosphorus. More complex compositions are available where special properties are required. A336 (Al–12Si–1Cu–1Mg–2Ni) contains nickel which forms stable intermetallic compounds. This alloy has improved elevated temperature properties, a low thermal expansion coefficient, and improved wear resistance. This alloy is used as the piston alloy for internal combustion diesel engines and higher output engines.

Al–Cu Alloys

Although Al–Cu casting alloys were the first aluminum casting alloys to be extensively used, most of them have now been replaced by other alloys. The main reasons for the replacement of the Al–Cu alloys are that they have poor casting characteristics, poor corrosion resistance, and high specific gravities.

One of the most important characteristics of the Al–Cu casting alloys is that they have excellent elevated temperature properties. Alloy 238 (Al–10Cu–3Si–0.3Mg) is used to cast soleplates for electrical hand irons and has the required high hardness at elevated temperatures. Alloys 240, 242 (Al–4Cu–2Ni–1.5Mg), and 243 also have high strength and hardness at elevated temperatures and are used for diesel engine pistons and air-cooled cylinder heads for aircraft engines. Good elevated temperature properties of these alloys come from the combination of

precipitation hardening together with dispersion hardening by intermetallic compounds.

The more recently developed 201 alloy has a particularly high response to age hardening, providing tensile properties significantly higher than those of any previous aluminum casting alloys. This alloy has the nominal composition Al–4.7Cu–0.7Ag–0.3Mg and is being used to cast premium quality aerospace parts. The high response to aging appears to arise due to the effect of silver on modifying the precipitation behavior expected for the Al–Cu–Mg system. Tensile properties of 345 MPa yield strength and 415 MPa tensile strength with a minimum elongation of 5% are guaranteed for the T6 tempered premium quality castings. These tensile properties are quite comparable to the properties of the high-strength wrought alloys. Like the other Al–Cu casting alloys, this alloy is also susceptible to stress-corrosion cracking in the T6 condition but resistance can be greatly improved by a T73 temper.

Al–Mg Alloys

Al–Mg alloys are characterized by high resistance to corrosion, good machinability, and attractive appearance when anodized. Controlled melting and pouring practices are needed since the presence of magnesium increases the tendency towards oxidation in the molten state. Most show little or no response to heat treatment.

The magnesium content of the binary alloys ranges from 4% to 10%. Most are sand cast although compositions with 7% and 8% magnesium have limited application for permanent mold and pressure die castings. The tensile properties and casting characteristics can be modified by the addition of alloying elements such as silicon, zinc, and manganese. However, these are not of major importance for the Al–Mg casting alloys because these alloys are used when corrosion resistance and decorative appearance are the essential requirements.

Al–Mg casting alloys are basically non-heat treatable. An exception is 520-T4 alloy (Al–10%Mg) which has an outstanding combination of strength, ductility, and high impact resistance. Slow quenching after solution-treatment is needed to provide optimum resistance to stress-corrosion cracking. The alloy tends to be unstable, even at warm ambient temperature, leading to the loss of ductility and resistance to stress-corrosion cracking after a period of time. Consequently, other alloys such as Al–Si–Mg tend to be preferred unless the higher strength and ductility of Al–10Mg are mandatory.

Al–Zn–Mg Alloys

The unique characteristic of Al–Zn–Mg alloys is their high melting points, making them suitable for castings which are to be assembled by brazing. The alloys also have good machinability, dimensional stability, and resistance to

corrosion. The alloys are normally sand cast because the use of permanent molds tends to cause hot cracking.

Al–Zn–Mg alloys in the as-cast condition show natural precipitation hardening behavior and their properties change rapidly by aging at room temperature. These alloys are ideal for castings with shapes that are difficult to solution treat and quench. The alloys are not recommended for use at elevated temperatures because overaging causes rapid softening.

ACKNOWLEDGMENT

The author is grateful to Dr. J.K. Oh, Prof. S. Lee, Dr. S. Ahn and Prof. D.H. Kim for their support during the preparation of the manuscript.

Die Casting Process Design

Frank E. Goodwin

International Lead Zinc Research Organization, Inc., Research Triangle Park, NC,
United States

Abstract

Pressure die casting is a process in which molten metal is forced under high pressure into a cavity in a metal die after which it rapidly solidifies. This high speed process allows complex shapes to be cast into net shape requiring minimal machining and finishing. This article reviews: basic die casting processes, shot system design, construction and use of the P-Q2 Diagram, feed system and overflow design, die machine selection, runner and gate systems, cooling systems and heat transfer, determining input values for water line placement, and application examples.

Keywords: Dies; Heat transfer; P-Q2 diagram; Sprue; Ψ - and β -values; Thermal conductivity.

THE DIE CASTING PROCESS

Pressure die casting is a process in which molten metal is forced under high pressure into a cavity in a metal die in a few milliseconds, after which it rapidly solidifies. The die is then opened and the casting ejected from the die. This high-speed process allows complex shapes to be cast to net shape, or nearly net shape, requiring minimal finishing and machining. Thousands, and in some cases millions, of castings can be economically produced from a single die set.

Basic Die Casting Processes: Hot Chamber and Cold Chamber

There are two basic die casting processes: hot chamber and cold chamber. The hot chamber process is used for lower melting point metals such as zinc and lead. The cold chamber process is used for higher melting point metals such as aluminum, magnesium, and brass. However, some magnesium alloys can be hot chamber die cast, while zinc alloys with higher aluminum content are cold chamber die cast.

Hot Chamber Process

The basic components of a hot chamber die casting machine and die are illustrated in Fig. 1. In this process, the plunger and the cylinder are submerged in the molten metal in the holding furnace. The power to pump zinc into the die cavity is provided by a hydraulic or air powered accumulator, with hydraulic being the most common. The hydraulic oil is supplied to the accumulator by a pump at a rate that will bring the accumulator pressure up to the desired operating level each time a casting (shot) is made.

The casting sequence in the hot chamber process is illustrated in Fig. 2. When a shot is made, the control valve opens, causing the shot cylinder to force the plunger down and molten metal through the nozzle, past the sprue pin, through the runners and gates, and into the die cavity. This molten metal displaces the gas contained in the runner system and the die cavity and this gas, together with some of the molten metal, flows through the die cavity and out through the vents, or into overflows. After the cavity is filled, the metal is allowed to solidify, the casting ejected, and the cycle is repeated. Because the gooseneck and plunger are submerged in the molten metal, the system automatically refills when the plunger is withdrawn. The length of the casting sequence (cycle time) is dictated by the ability of the die set to extract heat from the solidifying metal, and ranges from 1 sec for miniature castings to several minutes for larger, thick castings.

Cold Chamber Process

The casting sequence for the cold chamber process is illustrated in Fig. 3. In this process, molten metal is ladled into the cold chamber, either manually or automatically, after which the plunger advances to force the metal into the die cavity. Except for the manner in which molten metal is fed into the shot system, the casting sequences for the two processes are similar. The cold chamber process is used for casting metals that would attack injection system hardware, necessitating minimal contact between them. Cycle times are similar to the hot chamber process.

Die Casting Dies

Die casting dies consist of two parts, the cover (stationary) half and the ejector (moving) half, which meet at the parting

Fig. 1 Basic components of a typical hot-chamber, die-casting system

Fig. 2 Operating sequence for the hot-chamber, die-casting process. (a) Die is closed and hot chamber (i.e., gooseneck) is filled with molten metal. (b) Plunger pushes molten metal through gooseneck and nozzle and into the die cavity. Metal is held under pressure until it solidifies. (c) Die opens and cores, if any, retract. Casting stays in ejector die. Plunger returns, pulling molten metal back through nozzle and gooseneck. (d) Ejector pins push casting out of ejector die. As plunger uncovers filling hole, molten metal flows through inlet to refill gooseneck

line. The basic components of the hot chamber die casting die are shown in Figs. 1 and 2. The cover half of the die is secured to the front or stationary platen of the machine. The sprue for filling the die cavity is in this half and it is aligned with the nozzle of the hot chamber machine. The ejector half of the die is attached to the movable platen of the machine. It contains the ejection mechanism and in most cases the runners, as shown in Fig. 2.

The die cavity, which forms the part being cast, is machined into both halves of the die block or into inserts that are installed in the die blocks. The die is designed so that the casting remains in the ejector half when the die opens. The casting is pushed out of the die cavity with ejector pins that come through holes in the moving die half and are actuated by the ejector plate, which is powered by the machine. Guide pins extending from one die half

Fig. 3 Operating sequence for the cold-chamber, die-casting process. (a) Die is closed and molten metal is ladled into the cold chamber. (b) Plunger pushes molten metal into die cavity. The metal is held under pressure until it solidifies. (c) Die opens and plunger advances to ensure casting stays in ejector die. Cores, if any, retract. (d) Ejector pins push casting out of ejector die and plunger returns to original position

enter holes in the other die half as the die closes to ensure alignment between the two halves.

Dies that produce castings with complex shapes may contain stationary and movable cores. The movable cores are moved by cam pins or hydraulic cylinders and are locked in place when the die is closed.

Because die casting machines operate at high rates of speed heat must be removed from the die at a sufficiently high rate. Removal of heat is accomplished by circulating water or other coolant, typically oil, through channels drilled in the die blocks. Heat is sometimes added to the die by electric or gas heaters, or by heating the oil, for warm up or for making thin sections that transmit insufficient heat to maintain the die at the proper operating temperature.

Die Casting System Design Considerations

To produce high-quality castings, the die casting system must be designed to have the following characteristics.

- The shot system must be large enough to deliver sufficient molten metal to fill the entire die cavity when a shot is made.
- The complete system must be designed so that the cavity is uniformly and rapidly filled so that the cavity is filled with casting metal that has not started to solidify when flow stops. Otherwise, defects termed “cold laps” will result.
- The system must be designed to eliminate or at least minimize the entrapment of air in the die cavity when flow stops; otherwise, defects termed “blisters” will result.

DESIGN REQUIREMENTS FOR GOOD SHOT SYSTEM PERFORMANCE

To effectively utilize systematic design procedures for the runners, gates, and overflows required in die casting dies, knowledge of the shot system performance of the specific machine on which a die will be used is required. The shot system performance is characterized on a graph plotting the metal pressure in the system vs. the square of the flow rate. This information can be used with design guidelines described in this chapter to design the feed system for dies that are likely to produce first-shot success and more effectively utilize the metal delivery characteristics of the casting machine. This design information is based on research carried out at the Australian laboratory CSIRO^[1] and the Canadian zinc producer Cominco Ltd.,^[2,3] together with early fundamental work carried out at Battelle Columbus Laboratories under sponsorship of International Lead Zinc Research Organization, Inc.^[4]

The P - Q^2 Diagram

The application of fundamental principles of fluid mechanics, together with suitable assumptions, allows development of a relationship between the available metal pressure in the injection system (P) and the resultant metal flow rate into the die cavity (Q). The following assumptions are made for development of the P - Q^2 relationship:

- Steady state or constant velocity flow of injected casting metal.
- Turbulent flow of casting metal.
- One-dimensional flow of cavity metal.
- The casting metal is incompressible and has constant density.
- The casting metal is fully molten and does not solidify during its injection into the die.
- There is no friction loss in the cylinder seals of the injection system.
- No variations in metal pressure occur because of metal inertia, inertia of mechanical components, or the dynamic characteristics of the hydraulic system.
- The accumulated pressure in the hydraulic system remains constant during a shot.

The invocation of these assumptions allows for a simple P - Q^2 analysis to be derived although they may only be partially valid during certain stages of the shot. The straight line P - Q^2 relationship usually applies over most of the shot stroke when the data have been averaged near specific points of interest to process designers. Discrepancies arise during times of high acceleration or deceleration, i.e., at the beginning or end of the shot.

By a plotting available casting metal pressure P on a linear scale vs. metal flow rate Q on a squared scale axis, an approximate straight-line relationship is established as is

shown for line P_sQ in Fig. 4. That line represents the pressure that the machine can develop as a function of flow rate and is called the machine-pressure characteristic (pressure available). The machine-pressure characteristic is a function of the hydraulic system of the machine, including the shot cylinder and plunger.

Line OA on the Fig. 4 graph is called the gooseneck-nozzle characteristic. This line shows the pressure required to produce a specific flow out of the machine and into the die (resistive pressure). Its position is a function of the hydraulic characteristics of the gooseneck and nozzle. If the data are taken to include the sprue, runners, and gates, then the complete feed system characteristic line can be obtained as shown by line OB in Fig. 4. These parts of the injection system, in addition to the gooseneck and nozzle, cause flow resistances that reduce the ideal flow rate below rates that would be calculated based on the measured “dry shot” speed of the machine. Metal pressure and flow rate for a given set of shot system parameters is defined by the intersection of the available and resistive pressure lines (points A and B in Fig. 4).

Depending on how the shot system is set up (hydraulic pressure, opening of shot valve, plunger size, nozzle opening diameter, and the sprue, runners, and gating configurations), the position of these lines can vary, as will be described in subsequent sections.

Shot System Instrumentation

Instrumentation Requirements

The data used to generate a P - Q^2 diagram can be obtained from shot traces, providing that proper instrumentation and transducers are used. Typical instrumentation required to obtain the necessary data is as follows:

1. High speed digital acquisition system, or multichannel oscillograph UV (ultraviolet) recorder. Because

Fig. 4 General P - Q^2 diagram configuration

the die casting shot is of only a few milliseconds, the information gathered will be high-frequency and transient in nature. This requires a data recorder with high-frequency response for shot system characteristic measurement, trouble shooting, and tuning. The following performance requirements are recommended for data recorders:

- Frequency range: 0–1500Hz, flat within 5% variation, full scale.
- Maximum 10% overshoot to step input. For extensive research and troubleshooting of extremely high speed die casting machines, higher frequency response to about 4000Hz or higher may be required. If only shot system characteristic measurements on larger machines are desired, a frequency range of 0–800Hz is probably acceptable. However, with lower frequency response, there may not be adequate information gathered for extensive troubleshooting of machine performance problems. High-speed digital transient or computer acquisition systems or FM tape recorders can also be used in conjunction with slower speed plotters or recorders to obtain the data. Data recording can also be performed on a two or more channel oscilloscope with a camera for permanent records. This method requires extreme care in setting up and can provide good results.

2. Shot-Cylinder-Position (Displacement) Transducer. Several transducer types are available that meet the specifications below. Two that have been used are the cable-driven potentiometer and the linear-variable differential transformer (LVDT). Other possible choices that might be used for this application are ultrasonic transducers, capacitive transducers, linear potentiometers, optical encoders, and magnetic encoders. Any position or displacement transducer should have:

- Frequency range 0–800Hz flat within 5% variation.
- Maximum 10% overshoot to step input.
- 50 G acceleration—following capability.
- Transducer stroke slightly longer than shot cylinder stroke.
- Very rigid mounting to prevent transducer errors from relative motion.

3. Velocity Transducer (optional). The requirement for velocity transducers are the same as those listed above for position (displacement) transducers. If a velocity transducer is not used, velocity information can be obtained by electronic differentiation of the displacement signal, or by graphically differentiating the recorded displacement signal.

4. Pressure Transducer (two required): Pressure transducers must be rugged to withstand the high peak overpressures of the end of the shot, yet have good resolution and frequency response to measure the pressure drops and fluctuations during fill. Both

strain gauge and piezoelectric types of transducers have been used and each has its own advantages. Strain gauge types work well with DC and are easily calibrated with a static pressure source and are reasonably tolerant of dirt and moisture. However, although the strain gauge types are not as rugged and tolerant of overpressure transients as the piezoelectric type, they have been successfully used. The piezoelectric type is rugged but has the disadvantages of not being tolerant of dirt and moisture and must be dynamically calibrated by rapidly applying or removing pressure.^[5] Special low-drift electronics must be used with piezoelectric transducers and grounding switches must be used for measurement "standby." When the measurement is to be enabled, the switch is opened. This procedure minimizes drift and is used for both instrument calibration and shot system measurement. Either type can be used if they are selected and used properly. Pressure transducers should have:

- 0–5000 psi (34.5 MPa) working range minimum. 0–10,000 psi (69 MPa) working range preferred.
- 20,000 psi (138 MPa) minimum overpressure capacity preferred.
- Frequency range 0–1500 Hz within 5% variation for strain gauge or DC types, 1–1500 Hz within 5% variation for piezoelectric types.
- Drift rate less than 100 psi/min (0.7 MPa/min). This is particularly important for piezoelectric transducers and signal conditioners.

Other types of pressure transducers that might be used are capacitors, tuned-variable-frequency, and variable reluctance transducers.

Instrumentation packages can be purchased as total systems from manufacturers, or individual components may be purchased and assembled to form assistance.

Transducer Installation

The transducers used to obtain the necessary data must be properly installed on the die casting machine and connected to the high-speed recorder. Figure 5 schematically illustrates where the transducer should be installed. To install the pressure transducers, caps must be made available in the shot cylinder inlet and exhaust lines and a shut-off valve should be included for ease of installation and removal of the transducers. Bleed valves should also be incorporated to remove air from the hydraulic lines after installation. These transducers should be located on or very close to the shot cylinder. Drilling and tapping a port through the side of the pipe flange where it attaches to the cylinder is usually acceptable. The velocity and displacement of the shot cylinder rod can be measured with a single unit that provides both signals through two separate electrical outputs or with a displacement transducer only,

Fig. 5 Typical transducer locations^[2]

with the velocity being calculated from the displacement data. For the cable-driven potentiometer, the cable can be attached to the shot cylinder tail rod, the side auxiliary rod, or to the plunger through the use of suitable brackets. The body of the unit is attached to any convenient non-moving part, often through the use of a bracket directly attached to the shot cylinder housing. The mounting bracket and transducer must be very rigidly attached; otherwise, any bracket motion or vibration probably will be misinterpreted as plunger motion in the data. Care should be taken to locate the transducers where they will not be overheated or damaged by other moving parts. Similarly, the cables that connect transducers to the recorder should be protected.

Instrumentation, Calibration, and Check Out

After the instrumentation is assembled, it must be calibrated before use according to the manufacturer's instructions. Check out of the instrumentation is usually performed by comparing indicated singles with other measured parameters to know with certainty that the indicated measure corresponds with the measured parameter. Calibration and check out will assure that the measurement system is providing the necessary data to assess the performance of the shot system of the die casting machine.

Interpretation of Shot System Data

The information used to assess the shot system performance is obtained by recording the response of the transducers when castings are made. An example of the traces so obtained is shown in Fig. 6. Certain events during the shot are noted on this figure. However, determination of

the start or the end of the shot are usually obvious from the response of the transducers to determine when the metal reaches the sprue or when the gate requires a less direct approach. First, the full casting shot is weighed, and then the sprue and runners are removed at the gate and the casting is reweighed. Those weights are converted to volumes and then to corresponding plunger displacements. Then, those displacements are measured back from the end of the shot along with the displacement trace to locate the two points. These points will identify the various portions of the shot that are used when obtaining data on pressure and velocity at important stages of the shot for calibration purposes. They are also useful to obtain the cavity fill time, which is simply proportional to the distance between the gate point and the end of shot point if there are no overflows. If overflows are present, the cavity fill time can be determined by measuring the cavity volume and overflow volume and back calculating from the end of shot point. The plunger velocity during the cavity fill portion of the shot can be used for calculating the nominal gate velocity. That calibration is performed by multiplying the plunger velocity by the plunger area to obtain the volume flow rate of the metal and dividing the flow rate by the gate area.

Fig. 6 Simplified instrumentation traces of an injection cycle (shot valve on inlet, no slow shot). (a) Plunger displacement corresponding to filling the die cavity. (b) Plunger displacement to bring metal front from nozzle to gate. (c) Velocity can be obtained from the slope of the displacement curve ($\Delta X/\Delta t$) if a velocity transducer is not used

Careful examination of the shot traces will often reveal malfunctions or anomalies in the machine operation. Thus the instrumentation provides a very useful troubleshooting tool for production problems and machine maintenance.

A specific method for interpreting shot system data has been developed that is able to be programmed into a computerized data collection system.^[6] This system is used to calculate the dry shot speed and discharge coefficient of the shot system at either the nozzle or the gate. The discharge coefficient is a measure of the difference between actual and ideal flow. Factors that reduce the discharge coefficient of the feed system are surface roughness, sharp turns in the flow path, and sudden changes in the cross-sectional area of the flow path. This systematic method is similar to the method used by consultants to interpret shot traces.

Determining P - Q^2 Diagram for a Specific Machine

After the instrumentation described above has been attached to the machine and shot traces have been obtained, the P - Q^2 diagram for the machine can be determined.

Machine Characteristic Line

The line ($P_s Q$) in Fig. 4 is specified by two points: the static metal pressure P_s and dry shot speed flow rate Q . The metal pressure at any time during the shot is calculated from the following general relationship:

$$P_3 = (P_1 A_1 - P_2 A_2) / A_3 \quad (1)$$

where P_1 = pressure at the top of the shot cylinder; P_2 = pressure at the bottom of the shot cylinder; A_1 = area of the top of the shot cylinder piston; A_2 = area of the bottom of the shot cylinder piston; A_3 = area of the plunger; P_3 = metal pressure.

Ideally, the pressure P_1 is the average accumulated pressure that is available during the shot. In most modern machines, the accumulator pressure should vary less than 10%; therefore the accumulator pressure could be measured with a calibrated gauge at any time and that value can be used for P_1 without introducing significant error. However, for best results, P_1 should be determined by using the pressure transducers to immediately measure the hydraulic system pressure before and after the shot and averaging the two values. The accumulator pressure before the shot is usually measured on the rod end of the cylinder (actually P_2 before the shot is made) and after the shot on the head of the cylinder (P_1). Usually, for purposes of plotting the P - Q^2 diagram, P_1 and P_2 are measured at the end of the shot at which time $P_2 = 0$. Then, Eq. 1 is simplified to:

$$P_s = P_1 A_1 / A_3 \quad (2)$$

where P_s is the static metal pressure.

The dry shot speed can be determined by disconnecting the plunger and measuring the speed of the shot cylinder ram or rod and calculating a theoretical maximum flow rate for the plunger size from the following relationship:

$$Q = VA_3 \quad (3)$$

where Q = maximum flow rate; V = shot cylinder ram velocity (dry shot speed); A_3 = area of plunger.

In most cases, dry shot speed is not directly measured, especially in larger machines, because of potential damage to the shot system. Instead, intermediate points are determined from information from the shot traces and the dry shot speed or flow rate is determined by extrapolation. For example, points A and B shown in Fig. 4 can be calculated from the measurements of the pressures and velocity when the metal leaves the nozzle or the metal reaches the gates, respectively. The data for those points are determined by measuring back appropriate distances on the shot trace from the end of the shot based on the volume of the casting and the volume of the runners and sprue. Corresponding pressure and flow rate values could be calculated at other points in the shot; however, for most machines, all of these points should fall on the machine characteristic line. If the shot system has high pressure transients or significant internal effects (both of which violate the assumptions used to develop the P - Q^2 analysis), a die with a large cavity volume may have to be used during calibration to assure steady-state flow conditions can be achieved. Extrapolation of the line beyond points A and B then defines the dry shot flow rate (Q).

The slope of the machine pressure characteristic line ($P_s Q$) is a function of the flow area (or size) and the flow coefficient (or efficiency) of the hydraulic circuit. The partial closing of the shot valve acts to restrict the flow of hydraulic fluid, as illustrated in Fig. 7. Therefore when

Fig. 7 Effect of machine parameters on the P - Q^2 diagram. Effect of restricting hydraulic flow by the fast shot valve (reduces the metal flow rate)

assessing the performance of the shot system, the shot valve should be “wide open.” Increasing the hydraulic pressure causes the machine pressure characteristic line to shift upward, as illustrated in Fig. 8, but does not change the slope of the line. Changing the plunger size causes the position and slope of the machine pressure characteristic line to shift as shown in Fig. 9. Thus many parameters can affect the position and slope of the machine characteristic line, and changes in those parameters will influence the shot system performance.

Gooseneck/Nozzle Characteristic Line

Like any hydraulic system, the metal injection system of the die casting machine contains resistance to metal flow.

The pressure developed on the metal in the gooseneck during injection is that necessary to overcome the flow

Fig. 8 Effect of machine parameters on the P - Q^2 diagram. Effect of changing hydraulic pressure (increasing pressure)

Fig. 9 Effect of machine parameters on the P - Q^2 diagram. Effect of changing plunger size causes position and slope of machine-pressure characteristic line to shift

losses in the system. The pressure losses due to the flow of metal mainly result from friction and changes in flow configuration, such as changes in cross-sectional area and direction (bends) of the passages. Rough surfaces in the gooseneck and nozzle passages contribute to pressure losses due to friction and increased turbulence and thus may contribute to porosity in the castings.

The data that were used to calculate point A on the machine characteristic line of Figs. 4 and 10 were taken from instrumentation traces at the point where the metal was first exiting the nozzle (see Fig. 6). The calculated metal pressure at that point is that required to force the metal through the gooseneck and nozzle at that flow rate. Because zero pressure is required at zero flow rate, a line from the origin through point A defines the metal pressure requirements of the gooseneck/nozzle system. Because pressure is proportional to the square of the flow, the relationship can be shown as a straight line on the same graph as for the machine pumping rate. Line OA in Fig. 10 then defines the gooseneck/nozzle characteristic line (simply referred to as the nozzle characteristic line) and basically defines the square relationship between pressure and flow rate of molten metal flowing through the gooseneck and nozzle. Thus Point A defines a maximum flow rate available through the gooseneck and nozzle on that machine and the pressure define by point A also establishes the power consumed in the gooseneck and nozzle to achieve that flow. If the gooseneck and nozzle losses could be reduced (through redesign or by increasing diameters), the effective metal pumping capacity of the machine would be increased.

The pressure losses in a gooseneck can theoretically be calculated knowing the configuration and surface roughnesses of the internal passages, and methods for these

calculations are described in the literature. It is much simpler to empirically describe these “efficiencies” from instrumentation data. While only one point (other than the origin) is required, normally a number of points are calculated from the data taken at various shot valve settings. Therefore, nozzle characteristic line is usually a line of best fit through a number of points such as A, A', and A' in Fig. 10.

As was the case with the machine characteristic line, the slope of line OA is also a function of the flow area (or size) and flow coefficient (or hydraulic efficiency). However, in this case, the efficiency relates to the metal flow system instead of the oil flow system of the machine. A modified Bernoulli equation has been shown to be useful in calculating the hydraulic efficiency of different gooseneck/nozzle systems. The relationship between pressure and flow is:

$$P = \gamma Q^2 / 2GC_d A \quad (4)$$

where P = molten metal pressure in the gooseneck, psi (N/m² or Pa); γ = specific weight of the liquid metal alloy. For zinc, this is 0.221 lb/in.³ or 59,715 N/m³; G = gravity constant = 386 in./sec² or 9.8 m/sec²; Q = molten metal flow rate, cu in./sec (cu m/sec or 1000 L/sec); C_d = discharge coefficient, approximately 0.7–0.8 for well-designed system; A = area of the smallest part of the feed system, in.² (m²).

One of the key variables that affect the pressure/flow relationship in the gooseneck/nozzle system is the nozzle size. If the nozzle is enlarged, a greater flow results and conversely if the nozzle is reduced, then less flow occurs. Assuming that the discharge coefficient or value C_d of a gooseneck will remain constant with varying nozzle size, then Eq. 4 can be used to calculate nozzle characteristic lines for various nozzle sizes. This is accomplished by using the new nozzle area A and existing C_d value in the equation, assuming a Q value and solving for P . A line through the new pressure/flow rate point and the origin O determines the new nozzle characteristic line. This way, a series of characteristic lines can be calculated and drawn for a series of nozzle sizes as is illustrated in Fig. 11. The intersections of those lines with the machine characteristic line determine the flow rates that will be achieved for each nozzle.

Gate or Die Characteristic Line

A “gate characteristic line” is often included in the P - Q^2 diagram. It is similar to the nozzle characteristic line in derivation and meaning. It is also referred to as the “die characteristic line.” Just as the gooseneck and nozzle offer resistance to metal flow, so also does this sprue-runner-gate system. The data that were used to plot point B on the machine characteristic line (Figs. 4 and 10) were taken from data traces at the time representing metal

Fig. 10 Nozzle and die characteristic lines defined by various experimental P and Q points. Line OB shows the effects of flow losses in the total feed system

Fig. 11 Characteristic lines calculated for varying nozzle sizes (with the same discharge coefficient)

flowing through the gate or during the filling of the cavity (see Fig. 6). The calculated metal pressure at that stage represents the total pressure required to force the metal through the gooseneck, nozzle, sprue, runner, and gate at the flow rate that occurred. A line from the origin through point B (line OB in Fig. 10) defines the pressure/flow relationship requirements of the total metal system up to and including the gate. As was shown in Fig. 10, this gate characteristic line can also be a best fit for a number of points such as B, B', and B'.

The full losses of a metal flow system up to and including the gate are always higher than for the same system up to and including the nozzle. Thus the gate (or die) characteristic line always has a greater slope than does the nozzle characteristic line, meaning that greater pressure is required when metal flows through the gate than is required before that event. At the same time, the flow rate through the gate is lower than the flow rate through the nozzle before metal reaches the gate.

Increasing the feed system size (gate area, runner, sprue, nozzle) achieves a higher flow rate. Also, increasing plunger size would change the machine characteristic line, as was shown in Fig. 9. Figure 12 illustrates the relationships between the feed system size and plunger size. As is shown, the use of a small feed system with a small plunger may increase flow rates in certain regimes of the diagram (point B') in Fig. 12. The figure also shows that the use of a larger feed system (larger gate area) with a larger plunger (consistent with the design rules to be discussed in a subsequent section) will result in increased flow rates in other regimes (point A). For large, difficult to produce castings, it is desirable to fill the cavity in the shortest possible time. Thus the shot system configuration that results in higher possible flow rates should be used. This might be achieved by using a large feed system and large gooseneck and plunger as shown in point A in Fig. 2.

Fig. 12 Shot-system performance as a function of machine characteristics and feed-system characteristics

The equation for calculating the nozzle discharge coefficient can also be used for calculating the gate discharge coefficient; however, area A used in the equation should be the smallest cross-sectional area of the complete metal flow system. The gate area must be the smallest of the system; therefore it should be used in the equation for calculating the gate discharge coefficient.

Metal-Velocity Lines

After constructing a P - Q^2 diagram, it is often useful for die design considerations to add a family of lines corresponding to metal velocities as illustrated in Fig. 13. Velocity values are arbitrarily selected but they should be within a reasonable and typical range such as 80–150 ft/sec (24–46 m/sec). A number of nozzle characteristic lines, for nozzle areas appropriate for the machine in question,

Fig. 13 Calculated metal velocity lines and typical design boundary of P - Q^2 diagram shown shaded

are generated on the P - Q^2 diagram as was described earlier. By multiplying a selected velocity by each nozzle area, corresponding flow rates are determined. The points on the nozzle characteristic lines corresponding to the calculated flow rates are points on the line for the selected velocity.

These velocity lines indicate metal velocities in the nozzle over the range of nozzle sizes considered. If certain assumptions are made, then the calculated metal velocities can be assumed to be gate velocities for various gate areas (substituting gate area for the nozzle area based on the use of designed systems where no cross-sectional area in the feed system beyond the nozzle will be larger than the nozzle area). Obviously, there will be some error in gate velocities determined in this manner, but if the die is built to minimize flow losses, the errors will be small and this becomes a useful technique for die design (sizing of the sprue, runners, and gates).

The shaded area on the P - Q^2 diagram of Fig. 13 shows how velocity lines together with the machine characteristic line and nozzle characteristic lines could serve as boundaries, defining a region within which the designer could work.

For example, on the diagram shown in Fig. 13, the machine characteristic line for the “normal” hydraulic system setup is represented by line P_sQ . P_sQ' shows the machine characteristic line obtained if the hydraulic system pressure were increased, if that is possible. Other machine characteristic lines could be plotted on the diagram. For example, lines obtained for different-sized goosenecks or lines obtained with different shot valve openings could be shown. Lines OA through OE or OA' through OE' represent the effect of increasing the nozzle size on the metal pressure and flow rate at the nozzle exit. The shaded area then represents an attempt to define practical ranges of operating conditions for the machine. That area is defined by (1) the upper limit of nozzle/gate size OE or OE' , or (2) the lower limit of nozzle/gate size OA or OA' . The largest and smallest allowable gate areas will be determined by allowable gate thicknesses and practical gate lengths. A further restriction on the maximum gate area is that the gate area cannot exceed the nozzle or sprue inlet area.

Figure 13 shows that for the selected machine setup to achieve the machine characteristic line P_sQ , it would be impractical to achieve a gate velocity above 140 ft/sec (43 m/sec) with the smallest allowable gate area. If for the system it was determined that a 150 ft/sec (45 m/sec) gate velocity should be used, this could be achieved only by increasing, if possible, the hydraulic system pressure shown by line P_sQ' and by using a feed system with a small cross-sectional area.

With that higher system pressure, only low flow rates could be achieved with the small feed system. If it were determined that a very high flow rate was required to produce a large part with a short fill time, Fig. 13 shows the feed system would have to be large and only moderate gate velocities would be achieved with the large feed system.

If in designing the system it were determined that both a high flow rate and high gate velocity were desired, a machine with higher capacity shot system would be required than the one hypothesized in Fig. 13. The results of the research conducted at Battelle Columbus Laboratories^[4] indicated that to produce large castings with high surface quality, cavity fill time should be minimized (flow rate should be maximized). On the other hand, the Australian feed system design approach^[1] attempts to achieve specific velocities and will accept longer fill times (lower flow rates) to achieve that velocity. Unfortunately, limits on acceptable and unacceptable cavity fill times at specific gate velocities have not been reported. However, the normal limits of gate velocity suggested are 100–150 ft/sec (30–45 m/sec).^[7]

After the performance of the shot system of the die casting machine has been assessed, the information is used to design the runner and gating system (feed system) and overflow system for the casting. Two systematic approaches to design of the feed system will be described in the next section.

FEED SYSTEM AND OVERFLOW DESIGN

The objective of any method for designing the feed system of a die casting die is to produce high-quality castings with first-shot success. In any such system, great emphasis is placed on the control of molten metal flow and velocity through the feed system.

The first fundamental rule in designing the feed system is that the cross-sectional area of molten metal flow from the plunger to the gate should be constant or converge (become smaller). In the hot chamber die casting machine, traditional cast gooseneck design provides converging areas from the plunger to the gooseneck outlet. From that point, the cross-sectional area should remain constant or continue to converge; that is, the nozzle flow passage should be no larger than the gooseneck outlet, the sprue area should be no larger than the nozzle area, the total runner area should be no larger than the sprue area, and the total gate area should be no larger than the runner area. For cold chamber machines, the shot sleeve design is substituted for the gooseneck design consideration in this rule.

All systematic approaches attempt to provide uniform flow through the feed system by employing large and smooth radius turns rather than sharp corners. Sudden changes in cross-sectional area or sharp turns in the runner will cause flow separations with resulting turbulence and possibly soldering of casting metal to the die surface.

Such turbulence increases flow resistance and decreases the flow rate. It may also lead to die erosion. In addition, turbulence, especially when caused by sudden increases in cross-sectional area of the feed system, contributes to air entrapment in the metal and consequently less than desirable casting quality because of the formation of blisters and porosity in the casting. Turbulence also may result in

cavitation, which reduces die life. The following design guidelines are aimed at efficiently controlling flow of the molten metal alloy through the feed system to the die cavity with minimal mixing of molten metal and air:

1. Determine machine shot system performance; this one of the bases for both machine selection and die design calculations.
2. Make the cross-sectional area of the feed system constant or convergent from plunger to gate.
3. Fill the die cavity in the shortest practicable time, using acceptable gate velocities.
4. Proportion the gate (distribute the metal flow) according to the metal requirements of various segments or sections of the cavity.
5. Use runner-type sprues or cross-sectional area sprues, tapered tangential runners, or fan gates (of constant or reducing areas). The dimensions of all components that are defined and discussed in subsequent sections are calculated to obtain desired cavity fill times and metal velocities.
6. Determine size and location of overflows according to metal flow in the cavity and the anticipated die temperature. Attempts to eliminate overflows or minimize their volume.

The following sections outline the procedures used to design the feed systems for die castings in accordance with these general design guidelines.

Selecting the Die Casting Machine

Selecting the die casting machine on which to run the die being designed is primarily based on the clamping force required to produce the casting and the molten metal delivery characteristics of the machine's shot system. To determine the required clamping force, it is first necessary to determine the injection force. The injection force F_i is obtained by multiplying the projected area (A_p) of the die cavity, including runners and overflows by the final injection pressure P_f :

$$F_i = A_p P_f \quad (5)$$

The clamping force (F_c) of the machine should exceed the injection force by the following ratios:

Low-inertia injection system: $F_c/F_i = 1.25:1$.

High-inertia injection system: $F_c/F_i = 2.5:1$.

or

$$F_c = 1.25 \text{ or } 2.5(F_i) \quad (6)$$

A low-inertia injection system is one in which the accumulator is located adjacent to the shot cylinder, which is

typical of compact systems. A more traditional die casting machine (typically a high-inertia system) will have the accumulator located in the far end of the machine. In that case, high inertia is caused by the greater quantity of fluid in the longer hydraulic lines. That fluid must be suddenly stopped at the end of a shot stroke.

The machine should be able to deliver sufficient molten metal to achieve short cavity fill times and required gate velocities. Injection capability or metal flow rate is determined from the P - Q^2 diagram, as explained previously. The P - Q^2 diagram will show both the metal flow rate and metal velocity for the machine with several sizes of nozzles, as shown in Fig. 13.

The cavity fill time, which is the time required for molten metal to fill the cavity, assuming there are no overflows, is determined by the following relationship: where t_f = cavity fill time, sec; V_c = casting volume, cm^3 or in^3 ; Q = metal flow rate (cm^3/sec or in^3/sec).

$$t_f = \frac{V_c}{Q} \quad (7)$$

Recommended values for cavity fill time, assuming no overflows, range from 10 to 40 msec. The use of overflows increases the allowable fill time as discussed in a subsequent section.

The gate velocity that will be achieved with the shot system of the machine is calculated from:

$$V_g = \frac{KQ}{A_g} \quad (8)$$

where V_g = gate velocity (m/sec or ft/sec); Q = metal flow rate (L/sec or in^3/sec); A_g = gate area (mm^2 or in^2); K = constant, 100 for metric units, 0.083 for English units.

The recommended range for gate velocity (normal to the gate) is 30–40 m/sec. (about 100–150 ft/sec.). At this time, the die designer can determine the ranges of cavity fill times and gate velocities that can be achieved from the various nozzle sizes for the machine being considered. The cavity fill time is determined from Eq. 7 and by using the flow rates for the different size nozzles. The gate velocities can be determined from Eq. 8 and by using the nozzle bore cross-sectional areas or sprue areas for the gate areas if a constant area system is being designed, or the anticipated gate area, if a convergent feed system is being designed. Thus by considering the clamping force requirements and the shot system characteristics of the machines available relative to the desired cavity fill time, and/or gate velocity, the designer can select the machine and nozzle bore diameter that is best suited to produce castings in the die being designed.

Selecting a Runner and Gate System

The first step in designing a die using the design guidelines is to select and sketch the general configuration of the

runner, gating, and overflow system as shown in Fig. 14. There are usually several possible runner and gating configurations that might be used. Figure 15a, b illustrates two alternatives for one casting and Fig. 16 illustrates alternatives for other casting shapes.

When considered as part of the overall feed system, the position, shape, and dimensions of the gate determine the direction and velocity of the metal flow into the cavity and the flow pattern through the cavity. Correct design and dimensioning of all gates is essential to achieving high casting quality and overall casting efficiency.

Decisions on the positioning of gates relative to die cavity are subjective and are based on factors such as the shape of the casting, production requirements, and tooling costs among others.

General rules to follow in selecting the feed system configuration are:

1. Minimize runner length.
2. Provide uniform flow across the cavity such that air is forced out of the cavity ahead of the molten metal into overflows and/or vents.
3. Feed from the side with the most critical surface requirements.
4. Flow across the short dimension of the cavity, as shown in Figs. 15 and 16.
5. Avoid flow across large openings (consider center gating) or provide runners across large openings.
6. Select runner and gate configurations that control flow direction through the cavity so that metal flow tends to follow desired paths. This will be described in the section on segmenting and Fig. 17.

Although several alternative configurations can be used, as shown in Figs. 15 and 16, none will satisfy all the

Center gated casting

Side gated casting

Fig. 15 Alternative methods of gating a large casting with a large center opening

Fig. 14 Sketch of general runner, gate, cavity, and overflow configuration of a faucet-fixture casting

Fig. 16 A general guide of how to select a gating configuration for various typical casting shapes

guidelines listed. Therefore compromises must be made based on experience or other factors in the die design. To further illustrate how the metal feed systems might be selected, consider the casting shown in Fig. 15. For this casting, the die designer would have the following options for selecting the feed system:

1. Locating the sprue and runner system inside the opening (center gating) and locating the over-flows and/or vents around the outside parameter as shown in Fig. 15a.
2. Feeding from one side of the casting, placing runners across the opening, and placing over-flows and/or vents on the opposite side of the casting, as shown in Fig. 15b.

Either of these alternative configurations probably could be used to successfully produce this casting. The choice will depend to some extent on the casting size and configuration, but usually the preferred method of gating a casting of this type is to use the center gating technique shown in Fig. 15a. This configuration has the advantages that both runner lengths and flow distances across the mold cavity are minimized and the flow direction out of the gates will tend to conform to the anticipated flow pattern.

The only disadvantages of center gating are that the velocity of the metal flow tends to decrease as it progresses across the cavity, and a multicavity die cannot be used. However, these are usually not significant problems. In some cases, the reduction in the volume of the metal that

1) Keep cavity flow distance to a minimum, i.e. gate on longest side if possible.

2) Match filling pattern to casting shape so as to reduce turbulence to minimum.

3) Plan filling pattern to feed the most important features.

Fig. 17 General rules for selecting the gate and runner system

must be delivered to the die and cooled make it possible to achieve higher production rates with a center-gated, single-cavity die than can be achieved with an outside or side-gated, two-cavity die.

It should be noted that the feed systems illustrated in Figs. 15 and 16 are either constant or convergent in cross-sectional area to control metal flow to the die cavity.

If there are two or more large openings in a casting, the sprue should usually be placed in one of the openings and runners should be placed across the other large openings to carry the metal across them with minimal heat loss as shown in Fig. 18. If the second opening is not too large, it may be possible to flash across it and fill the portion of the casting beyond the opening. The side gate configuration illustrated in Fig. 15b could also be used for such a casting.

The feed system illustrated in Fig. 19 shows a converging flow system for the nozzle to the gate. Sharp corners are avoided and the surfaces are, or should be, smooth and well finished. In addition, the bore of the gooseneck should be sufficiently large to ensure low velocity through the major bends, to minimize pressure losses. The bore of the nozzle should be only slightly smaller than the bore

Fig. 18 Preferred method of gating a large casting with large multiple openings

of the gooseneck or shot sleeve outlet so that the velocity of the molten metal through the nozzle is maintained at low value. Again, low velocities, large radius turns, and smooth surfaces are used to keep pressure losses low.

Locating the Gate

Once the general configuration of the feed system is determined, the exact location of the gate should be established. Locating a gate involves the following variables:

1. Flow pattern in the cavity.
2. Flow distance in the cavity.
3. Casting and die configuration.
4. Surface finish requirements.
5. Air venting and/or overflows.
6. Trimming requirements.
7. Gate velocity.
8. Cavity fill time.
9. Die temperature.

The gate location and the gate area have a direct effect on the first eight factors. The machine injection system also affects the gate velocity and cavity fill time, and the die temperature has a significant affect on the casting surface finish. The main difficulty in selecting gate location is that these factors are so closely interdependent.

For example, the gate thickness, part thickness, and gate velocity can affect the metal flow behavior downstream from the gate. Depending on their values, the metal

Fig. 19 Converging flow system, showing single runner type sprue, main runner, tapered tangential runners, shock absorbers, and the gate to the die cavity

flow can be continuous or atomized, thus affecting the flow pattern in the cavity. In some cases, the complexity of the casting configuration and/or trimming requirements may be the only factors governing the location, length, and thickness of the gate.

Segmenting the Casting

As an aid to visualizing how metal will flow across the cavity, depending on the gate location, and to determine the metal requirements for various portions of the casting, a casting should be divided into segments. This segmenting should be performed for each alternative gate location considered. Typical examples of how casting might be segmented are shown in Fig. 20. General guidelines for segmenting are:

1. Use flow patterns that would tend to normally exist in the cavity, so that molten metal will tend to flow into a segment at an ingate, through that segment, and then flow out of that segment into an overflow. Because segment lines are only guidelines, flow totally within segment batteries will not exist during actual production except for the simplest casting shapes. In addition, the flow pattern in the cavity can be influenced by gate location and the angled metal flow out of the gate.
2. Minimize flow length in the segment.

Fig. 20 (a) Segmenting die castings for gate design calculations: Method of dividing water faucet casting into segments. (b) Segmenting die castings for gate design calculations: method of dividing mirror shell into segments

In many cases, it will be impractical to follow all of the rules for selecting both runner and gate segment configurations and so it will be necessary to make compromises. Although it may be necessary to sacrifice some of the desirable features in all but the simplest designs, following the design guidelines for segmenting above will, in general, provide flow conditions that will promote rapid and uniform filling of the die. Rapid and uniform filling of the cavity will minimize the formation of cold lap (cold shut) and blister defects. To control blister formation, flow across the cavity should be uniform to force the air out of the cavity ahead of the molten metal stream into overflows and/or vents. Of course, in practice, this condition is difficult to achieve because of changes in flow direction and section thickness that results from the configuration of the cavity.

Calculation of Gate Dimensions

To maintain the desired velocity of metal flow throughout the feed system and to fill a cavity in the shortest practical time, one should design the ingates so their total cross-sectional area is equal to or smaller than the smallest cross-sectional area in the die feed system from the gooseneck or shot sleeve to the die. This minimum area often occurs at the sprue. However, in some cases, it may occur at the nozzle in the hot chamber machine. When the latter condition exists, the nozzle size should be increased or the sprue size should be decreased to reduce turbulence and pressure loss between the nozzle and sprue. Based on the evaluation of the shot system performance and the desired fill time and/or gate velocity for the casting being considered, the nozzle diameter, hence the sprue or the die inlet area, will be defined, as was previously described in “Selecting the Die Casting Machine” section. That area should be used as the basis for the sizing of the gates. In addition, the area of the ingate for each segment should be sized in proportion to the volume or weight of metal in that segment.

If the gate area calculations are made on a weight basis, the weight of the casting and weight of casting metal in each segment must be calculated first. Alternatively, if the part to be produced already exists as a casting, it can be weighed and the segment weight determined by drawing lines on the casting, selling the casting into the segments marked, and weighing the segments. The maximum allowable gate area for each segment is then given by:

$$\text{Segment gate area} = \frac{\text{die inlet area} \times \text{segment weight}^{**}}{\text{total casting weight}^{**}} \quad (9)$$

Equation 9 defines the largest gates that can be used for the casting while at the same time keeping the gate small enough to control the pattern of metal flow into the cavity. Once gate location and length have been decided, the gate thickness should be made such that the desired gate velocity and cavity fill time are achieved. The limiting factors for gate thickness are that it can neither be thicker than the

casting nor can it be too thick for efficient trimming. The minimum practical gate thickness depends on the accuracy of control of the die temperature and other process variables. For example, higher die temperatures allow thinner gates to be specified. In practice, the minimum gate thickness is often determined by manufacturing and tolerance considerations, but gates as thin as 0.007 in. (0.18 mm) have been found to satisfactorily work.

To determine desired metal flow velocities, gate thicknesses in the range of 0.008–0.024 in. (0.2–0.6 mm) are common and the length is in proportion to the volume or weight of the casting, or segment of casting being fed by that portion of the gate.

After the cross-sectional areas of the gates for each segment are computed, the gate thickness is calculated by dividing that area by the gate segment length. If making the total gate area equal to the die inlet area results in gates that are too thick for normal trimming, the die designer should reevaluate the runner-gate configuration to increase the gate length. This procedure will generally reduce the gate thickness.

If the gate thickness cannot be reduced by a change in the runner-gate configuration, then the thickest gate sections should be reduced to the maximum thickness considered practical for trimming, and all other gate and runner areas should be proportionately reduced. For example, if the maximum calculated gate thickness were a segment or several segments was 0.050 in. (1.27 mm) and the maximum gate thickness considered practical for trimming was 0.025 in. (0.64 mm), then the thicknesses of the gates for each segment should be reduced to one-half of their calculated thicknesses. At this point, it may be desirable to consider reducing the nozzle and sprue areas to match more closely the gate area and thus minimize air volume in the feed system. Alternatively, the designer could gradually decrease the cross-sectional areas of the various components of the feed system from the nozzle to gate using the guidelines for a converging area system. These guidelines will be described in a subsequent section. As a general guideline, the total gate area should not be less than 40% of the die inlet area, or in a hot chamber machine, the nozzle exit, in a converging system.

Making the total ingate areas equal to the die inlet area may produce gates that are too thin to be practical. The die designer then has a choice of redesigning the system to increase the component sizes in the die inlet area, selecting another gating configuration to use a shorter gate (usually not a desirable approach), or using what some die casters have called a comb gate. A comb gate is a series of short, moderately deep gates instead of a long continuous thin gate. Figure 21 shows how a gate of this type would be constructed. If comb gates are used, the spacing between the gates should be equal to or less than the length of the gate opening to minimize the effect of the flow separation through the individual comb gates. However, continuous gates as long as 0.007 in. (0.18 mm) have been successfully used, as previously noted.

Fig. 21 Details of comb gates

Often, fan gates are used to distribute flow at the end of a runner. Figure 22 provides guidelines for designing a fan gate with the constant cross-sectional area. The design of a fan gate with decreasing cross-sectional areas is illustrated in Fig. 23. One of the advantages of the fan gate design shown in Fig. 23 is that it is relatively simple to machine. Also, the flow velocity is highest in the center of the gate, which is useful to achieving certain types of fill patterns. On the other hand, that design can lead to turbulence if carelessly performed and it is not suitable for wide fan gates.

Fig. 22 Design of fan gate with constant cross-sectional area

Determining Gate Velocity

After the ingate areas have been determined, the nominal velocity normal to the gate that will be achieved can be calculated from Eq. 8 presented earlier.

Gate velocity will usually fall within the ranges recommended by the North American Die Casting Association which are 90–150 ft/sec (27–46 m/sec). If the gate velocity exceeds the maximum value of that range, die erosion or soldering problems may be encountered. Hence the gate design or metal flow rate should be modified to reduce the gate velocity to be within the recommended range.

Figure 24 illustrates a typical converging feed system with tapered tangential runners feeding the ingates and the recommended metal velocities in each component of that system. Those velocities are determined by selecting the shot system configuration based on the P - Q^2 diagram that yields the desired velocity at the nozzle exit and then by sizing the other components of the system in accordance with the previously given guidelines.

The true gate velocity through the gates fed by tapered tangential runners is higher than the value calculated from Eq. 8. This is because of the variation in flow angle (that is, the angle between the normal to the gate and the metal flow direction) resulting from the dimensions of the tapered tangential runners as shown in Fig. 25. The true gate velocity can be approximated by the following relationships:

$$\text{True gate velocity} = \sqrt{\text{runner velocity}^2 + \text{gate velocity}^2} \quad (10)$$

where the runner velocity and gate velocity are calculated from Eq. 8, or:

$$\text{True gate velocity} = \frac{\text{gate velocity}}{\cos \theta} \quad (11)$$

where the gate velocity is that calculated from Eq. 8 and θ is the flow angle from the gate, shown in Fig. 24.

Should the feed system be designed to operate at reduced injection pressures, the true gate velocities for all reduced- and full-injection pressure should be calculated and recorded. The true gate velocity that would result if the machine were running at full injection pressure should be noted on the instructions to machine operators. If the value of the true gate velocity exceeds the recommended range, under any injection pressures, the operator should be warned that excessive gate velocities might cause die erosion if design parameters are exceeded.

Calculating the Runner Dimensions

In fluid flow systems such as runners and die casting dies, the flow efficiency, described by the discharge coefficient C_d applies. The discharge coefficient, as it applies to flow in the shot system of the die casting machine, was discussed earlier.

Fig. 23 Design of a fan gate with a decreasing cross-sectional area. W6 is normally 2 to 3 times T6 to provide better fan feed shape at the expense of heat loss

Fig. 24 Converging flow system, showing molten alloy velocity upper limits

The coefficient of discharge of the runner system is influenced by the configuration of the system including changes in cross-sectional area and changes in flow direction and friction between the flowing metal and the surfaces of the runner system. Sharp changes in flow direction, abrupt (stepped) changes in cross-sectional area, surface

roughness, and flow distance all contribute to reducing the flow efficiency or discharge coefficient.

Therefore the runners should be designed with constant or gradually reducing cross-sectional areas, large radius turns, short flow distances, and smooth (polished) surface finishes. However, even when all of these guidelines are

Fig. 25 Approximate flow angle variation with the ratio of the runner inlet area to the gate area

followed, the flow in the runner system will not be 100% efficient. Nevertheless, by following those general guidelines, the flow efficiency will be considerably better than that obtained in runner systems designed without following those guidelines. Unfortunately, many runner systems are still being cut in the dies with sharp turns, abrupt changes in flow direction, and no consideration for the cross-sectional area relative to those of the nozzle and the sprue or the gates.

For a constant area metal feed system, the drawing in Fig. 26 illustrates how the runner area calculations should be made for a tangent runner that is continuously feeding metal through the gate. As is shown, the runner cross-sectional area at any point is merely the sum of the cross-sectional areas of the segment gates being fed by that runner. The figure also shows the location of the areas used in the calculations. This summing procedure is used for all runners back to the minimum die inlet area. Thus the total gate area cannot exceed the minimum die inlet area and the total cross-sectional area cannot exceed the minimum inlet area. Furthermore, as seen in Fig. 26, the use of this technique results in a natural taper in the tangent runners, and those runners taper to zero cross-sectional area at their ends. If correctly machined, the taper virtually eliminates high transient metal velocity and resulting shock during filling of the runner. Shock absorbers can also be used to eliminate shock during runner fill. Design guidelines for shock absorbers will be presented in a later section.

Fig. 26 Method of calculating runner area in a constant cross-sectional area feed system

If the constant area runner system has long flow distances and several changes in flow directions, flow losses may occur such that the coefficient of discharge of the runner is in the range of 0.6–0.8. In those cases, the metal flow rate through the gate will be less than that calculated based on the metal flow rate exiting the nozzle. Thus the cavity fill time will be somewhat longer than the value calculated and the gate velocity will be lower than that calculated based on the flow rate exiting the nozzle. These factors could result in lower casting quality than anticipated.

Because of those possibilities, it may be preferable to design the runner system with a converging (decreasing) cross-sectional area. Figure 27 illustrates that type of runner system and provides guidelines for the reduction in cross-sectional area through the various sections of the runner system. General guidelines for the reductions in cross-sectional area for a converging system are as follows:

1. Decrease cross-sectional area 10% in straight sections such as along the sprue or along the main runner.
2. Decrease cross-sectional area 20–30% through turns, depending on the radius; the smaller the radius, the larger the reduction in area.

3. Short runners in the sprue or short main runners may be constant area.
4. The inlet area of the taper tangential runner should be 1.2 times the area of the gate fed by that runner. Depending on the desired flow angle into the cavity, this area ratio can be altered. See Fig. 25 for flow angle relationships.

Regarding the flow angle into the cavity, ratios of tangent runner areas to gate area of 1.1–1.2 will provide a flow angle into the cavity of 40–45° from the normal to the gate. If larger runner inlet areas are used, the runner velocity is decreased and the flow angle into the cavity will be closer to normal to the gate. For example, with a runner inlet area equal to twice the gate area, the flow angle will be about 30°. However, using a heavier runner will result in more metal to remelt after trimming.

Following the design guidelines for a converging cross-sectional area runner system will result in gate areas that typically are in the range of 40–60% of the nozzle area. The runner system with a decreasing cross-sectional area results in a greater latitude in achieving adequate die performance with the die casting machine whose flow efficiency discharge coefficient may be low or unknown.

Fig. 27 Converging flow system, showing single runner type sprue, main runner, tapered tangential runner, shock absorbers, the gate to the die cavity, and the typical areas of the various components of the runner system. General rules: (1) Decrease area 10% in straights (such as along sprue runner or main runner). (2) Decrease run 20–30% around bends, depending on severity. (3) Short runners in sprue or main runner may be constant area. A_n = Nozzle area; A_c = sprue area; A_m = main runner area; A_t = tangent runner area; A_g = gate area; A_c = tangent runner end area

There are two additional features that are typically used with converging runner systems as shown in Fig. 27. Those features are the shock absorbers and the delta region. The tangential runners typically terminate in 0.4 in. (10 mm) long sections with a 0.079 in. (2 mm) square cross section that enters disk-shaped shock absorbers. The use of shock absorbers is recommended to control very high transient metal velocities that may be reached at the small square ends of the runners, with consequent high energy release (shock) through the extremities of the gate. That high transient velocity may cause severe erosion damage to the die. The shock absorbers also protect the die when the gate does not completely fill, as in a cold die during startup. The shock absorber should be cut 0.079 in. (2 mm) deep and its top (circular) area should be the same as the area at the entry to the tapered runner. Figure 28 shows the design guidelines for shock absorbers.

The delta region between the tangential runners shown in Fig. 27 feeds the central portion of the castings. The delta is often initially cut to the preselected gate depth. The flow in that region is then assessed during the initial casting trial. The delta region may then require modification to achieve proper flow in that region. The design guidelines for the delta region area are illustrated in Fig. 29.

Determining Shape of Runners

After the runner areas have been calculated, runner cross-sectional configurations are selected that:

1. will minimize heat loss from the runners
2. will cool rapidly enough so that high production rates can be obtained
3. can be easily machined
4. are easily designed
5. have sufficient draft so that the casting can be easily ejected

When long runners (at least 200 mm or 8 in., or longer) must be used, it is usually desirable to make the cross section of the long portion of the runners round to minimize heat losses. However, for practical reasons (economy, machinability), a rectangular (actually trapezoidal to allow draft for good ejection) configuration with depth equal to width is usually recommended. When short main runners are used, wide, shallow, rectangular (trapezoidal) runner sections are usually desirable to maximize the heat transfer from the runner and to maximize the production rate. “Design of The Cooling System for Die Casting Dies” section, on die cooling systems and water line placement, gives information on determining the production rate that can be obtained with different size runners. At locations where runners split, it is usually desirable to make a rectangular (trapezoidal) runner section so as to minimize machining difficulties. Figure 30 shows how these features were employed in the design of one die and it shows one method of designing a runner with variable cross-section shapes.

Experience has shown that in most cases, the runners should be defined and described (at least the details shown in Fig. 31). In traditional practice, the runner system was first modeled in wood or other suitable medium first and then checked by the designer before the die was cut. This minimized costly machining errors. Use of computer-aided design techniques obviates the need for this modeling; however, careful checking of compatibility should be made before beginning die machining.

Selecting the Sprue Configuration

The constant or decreasing cross-sectional area rules should be followed through these sprue base and sprue. Standard sprue pin and bushing sets that have constant cross-section area are commercially available. Alternatively, a runner sprue can be designed and used to maintain constant area through the sprue. The use of runner sprues gives the designer added flexibility in that the

Fig. 28 Design guidelines for runner shock absorber. The runner shock absorber prevents the “spurt” of metal that would occur at the end of the runner just as it fills. Shock absorber diameter should be sized to give area of shock absorber face (A') = area of start of tangent runner (A)—see diagram. The area of entry into the shock absorber should be 2×2 mm

Fig. 29 Design guidelines for the delta region

runner channels can be made to various configurations, such as a round, half round, or rectangular (trapezoidal). Figure 32 illustrates a rectangular runner sprue and the cooling system normally applied. The shape of the flow path is good, metal flow characteristics are excellent, and the transitional curve into the runner has a relatively large radius. It is a simple design, but more expensive to make than a conventional fully turned sprue.

Runner sprues can be easily cut with a modified keyway (Woodruff) cutter, as shown in Fig. 33. To produce such a rectangular shape in a runner sprue, one should turn the cone shape of the sprue pin 0.010–0.020 in. (0.25–0.55 mm) less than the main cone of the sprue bushing. Channels are then cut into the sprue pin by use of the Woodruff cutter ground with appropriate draft angles on its sides. The included angle of the cone in the sprue bushing

Fig. 30 Cross sections through different segments of the runner-and-gating system used with the TV-bezel dies. Four runners were used to bring liquid metal into the diagonal corners of the die cavity

should be a minimum of 20°. Blank sprue pins in which the runners can be cut are also commercially available. Cooling of the sprue is carried out as with conventional sprues; however, cooling of the bushing may not be required. If cooling is required, it can usually be accomplished by a fountain under the runner region in the sprue pin.

Overflow System Design and Vents

Should overflows be necessary, as is usually the situation for parts where surface finish is critical, their locations should be determined by examination of the flow patterns that exist in the casting. Such overflows can serve four important functions in the casting:

1. They are reservoirs that receive and hold gasses flushed out of the cavity.
2. They are reservoirs for cold and oxidized metal that initially flows through the cavity.
3. They provide additional heat input to the die, therefore helping to maintain a satisfactory and stable die temperature.
4. They serve as locations for contact of ejector pins when the ejector pin marks are not permitted on any surface of the casting.

Fig. 31 Dimensions of gates used with the modified TV-bezel die

The first three functions help to eliminate blisters and cold laps. Overflow gates and overflows have been found to be very effective vents because large quantities of gasses flowing ahead of and mixed with the initial metal flowing into the cavity can be made to pass through the overflow gates, which are generally thicker and shorter than vents. Traditionally designed vents are usually thin clearances with a long flow length cut between the die halves to allow the gasses to escape from the die cavity. However, as soon as a small amount of molten casting metal reaches the small vent openings, it often solidifies and prevents further flow through the vents. On the other hand, if the vents do operate, they can be very effective in allowing gasses to escape in front of the molten metal.

The use of constant area or converging area metal feed systems, with correctly designed runners, promotes the expulsion of air into the feed system ahead of the molten metal and through the cavity to the air vents. To promote expulsion of

that air from the cavity, vents with total areas of the 20% of the gate areas and with depths up to 0.039 in. (1 mm), as shown in Fig. 34, may be considered. Unfortunately, there has been very little research directed at optimizing vent design.

By proper design, the overflow gates and overflows can be used effectively as vents, and most of the molten metal that initially flows through the cavity and contains most of the entrapped gasses can be forced into the overflows. Experience has demonstrated that when the proper runner, gating, and overflow designs are used, blisters can be eliminated from die castings.

If the castings produced during the first trial run show poor surface finish or blisters, the following should be checked first:

1. Machine operation and performance.
2. Feed system design and dimensions.
3. Die temperature.

Fig. 32 True runner type sprue, showing smooth flow path and large radius for transition into main runner. Area chart shows converging flow path

Fig. 33 Use of a woodruff cutter to cut the runner into the sprue pin

This checking should indicate that both the machine and die are operating according to the values of parameters used in the design. If they are not, appropriate modifications should be made to ensure that the design values are being achieved.

The size of overflows will depend on the types of defects in the casting and on the degree of die heating required from the increased mass of molten metal. A further consideration is the distance of the molten metal travel through the feed system and cavity. Where long flow distances are unavoidable, large overflows may be necessary.

Overflows may be necessary in the open center of ring-shaped castings feed around portions of their outer parameter from tapered tangential runners because air vents may be difficult to provide in such areas.

Some analytical studies have been conducted to aid the die caster in determining the size of overflows required to produce cold shut free castings. These studies show that if sufficient molten metal flows across the surface of the die and into an overflow, the surface of the die is heated and only molten metal remains in the cavity when flow stops. Consequently, all the partly solidified metal will be flushed from the cavity and cold lap (cold shut) defects will be eliminated. As the casting thickness is reduced, the tendency for cold lap defects increases because less metal, and therefore less heat, is put into the die. Also, for a given surface area of casting in the die at a given temperature, the temperature of the metal in a thinner casting will be reduced more rapidly because of the shorter heat transfer path (reduced section thickness). These problems can be overcome by use of higher die temperatures, shorter cavity fill times, or the use of larger overflows.

Guidelines for determining the size of overflows required to produce cold lap free castings were an outgrowth of those studies that were followed by further laboratory and field studies. The first guideline that can be used when redesigning an existing casting to reduce its wall thickness is to take the volume or weight of the metal that was eliminated by reducing the section thickness and place it in the overflows. For example, if a casting with a wall thickness of 0.079 in. (2 mm) in weight of 2.2 lb (1 kg)

		Dimensions, mm	Total area, mm ²

	D ₁	10 × 10 = 100	
	D ₂	7 × 7 = 49	249
Gate		600 × 0.335	201

Fig. 34 Flow system details with dimensions and areas

has been successfully produced using 1.1 lb (0.5 kg) overflows, that casting can probably be successfully produced with a wall thickness of 0.040 in. (1 mm) and a weight of 1.1 lb (0.05 kg) by increasing the overflows to 2.2 lb (1 kg).

The general guideline was augmented by computer studies to determine the size of overflows required with a fixed set of die casting parameters. The casting parameters and the assumed values were:

1. The capacity of the die casting machine, assumed to be sufficient to pump 600 in.³ (9700 cm³) of zinc per second.
2. The die material, assumed to be P-20 hot work tool steel.
3. The runners, assumed to be four in number, round, and 0.50 in. (12.7 mm) in diameter.
4. No coating of any type on the die surface.
5. A holding temperature of 800°F (427°C).

With these parameters fixed on the indicated values, the cavity size, die temperature, runner length, and cavity fill time, which were varied in the corresponding overflow sizes, were calculated. Plots of the results show

the required overflow size as a function of cavity fill time for a given die temperature. Two such plots are shown in Figs. 35 and 36. One of the interesting observations from these plots is that the runner length can be an important parameter. Heat loss from long runners is appreciable and is detrimental to casting quality. So the die caster should make every effort to keep runner lengths short.

These studies also uncovered many instances of inadequate and/or contradictory descriptions of the thermal properties in the die casting system. Where this was the only kind of information available, worst-case assumptions were used. Therefore it is expected that by using the presented design curves, the die caster will be able to produce cold lap free castings with the overflow sizes calculated from these design curves. Because of the conservative assumptions that have been made, it may be practical to produce satisfactory castings with smaller overflows that would be calculated by using Figs. 35 and 36.

For example, a study conducted by investigators at the Gulf and Western Company's Natural Resources Group showed that virtually cold lap free castings 0.030 in. (0.7 mm) thick could be produced with overflows in zinc that were only 40% of the volume predicted when the curves given in Fig. 35 were used.

However, it is recommended that the die caster initially either construct dies with the size of overflows calculated according to these design curves, or at least allow room for larger overflows although initially smaller overflows (about one-half the size calculated) might be cut into the die. Then, during the die development period, adequate space will be available to enlarge the overflows to eliminate cold lap defects, if this approach is found to be necessary.

Fig. 35 Calculated overflow size required to prevent cold-shut defects with a die temperature of 260°C (500°F). [Cavity fill time calculated from Eq. 7.]

Fig. 36 Calculated overflow size required to prevent cold-shut defects with a die temperature of 277°C (530°F). [Cavity fill time calculated from Eq. 7.]

Discussion

Considerable attention has been devoted in this section to provide general and specific guidelines for designing feed systems for pressure die castings and a result was specifically given for zinc. As noted, they require a number of calculations to determine the dimension of the various components in the feed system. Adherence to the guidelines, and proper machining of the feed system in the die, should result in first-shot success and high-quality castings. Computer programs are now available from several sources such as the North American Die Casting Association that greatly simplify die design by eliminating many of the manual calculations and use of the graphs described in this chapter. However, they are based on the same principles.

DESIGN OF THE COOLING SYSTEM FOR DIE CASTING DIES

Introduction

In addition to being a mold that produces a casting with a desired shape, a die casting die is a cooling device that extracts heat from the molten metal—the heat is then liberated while the metal cools to the solidification temperature; the latent heat of fusion is released during solidification and the heat from the solid metal is then cooled to the ejection temperature is released. Heat is removed from the casting by conduction through the steel die, either to coolant passages where the coolant transports heat away, or to the external surfaces of the die where heat is lost by radiation or convection, or through connections to the die

holder and die casting machine that remove heat by conduction. The die performs the function of a heat exchanger in this way, and design considerations must be included in overall die design if good quality castings are to be made.

The die must rapidly remove the heat introduced during each shot so as to maintain an economical production rate; thus the heat-removal capacity of the die must balance the heat input to maintain the die temperature at the level required to produce satisfactory castings. The necessary cooling capacity, which may be different for various sections of the die, primarily depends on the section thickness of the casting, the production rate, and the type of surface finish required. When the optimum die temperature or die temperature balance has been achieved, it usually must be maintained within a relatively narrow range. In the production of thinner section castings with a high-quality surface finish, the control of die temperature may even be more critical than it is for castings with heavier sections.

To obtain the benefits inherent in automatic process controls, adequate cooling capacity must be designed into the die. To achieve that result, water line sizes and locations should be selected to provide more cooling capacity than will be required to cool the die when the die is at its maximum production. The die temperature then is maintained at the desired level by adjusting the flow of the coolant through the die by means of a temperature controller and solenoid operated valves.

In the die casting industry, the selection of the size and locations of cooling water lines has traditionally been left to the discretion of the die designer. In the majority of new dies constructed, that selection is based on the experience and judgment of the designer to provide proper cooling. The dies are then built and trial runs are made. If satisfactory castings cannot be made, water lines may then be added or deleted to lower or raise the temperature in selected portions of the die, or, in many cases, the machine production rate is decreased to compensate for inadequate cooling capacity of the dies. It is costly to conduct trial runs with the die, to add or eliminate water lines to achieve proper cooling, or to reduce the production rate because of inadequate cooling capacity. Also, the addition or elimination of water lines does not assure that optimum cooling conditions are obtained.

The determination of water line locations and sizes is a problem that can be solved through the use of computer analysis to simulate steady state heat transfer conditions. However, in many cases, the use of a sophisticated computer analysis is not necessary for determination of water line locations. High-quality die castings have been successfully produced with guidelines given below that ensure that adequate cooling capacity is available.

These guidelines depend on a steady state heat transfer analysis that is used to develop design criteria for the sizing and placement of cooling passages and dies. The configuration of die casting can be complex and vary from one

type of casting to the next. Therefore rather than develop a program that would handle complex shapes, two simple casting sections were considered in development of these recommendations. It was assumed that the casting was made of section that can be approximated by flat plates or strips. Even with those simplifications, the heat transfer analyses were formidable and required specialized computer programs. These programs used steady state heat transfer models whose description is beyond the scope of this chapter. The results of those computer calculations were analyzed to determine relationships among the imposed heating and cooling additions and resulting die surface temperatures. Depending on the particular casting and cooling configurations under consideration, the results were used to provide an equation for calculating the die surface temperature as a function of other parameters and graphs that relate die surface temperature and the other parameters.^[8]

Subsequently, to further simplify the effort required to determine the location of waterlines and dies, computer programs were written and are now widely available to the die casting industry through the North American Die Casting Association.^[9,10] However, because all users of this chapter may not have access to these programs, the equations and graphical solutions initially developed from that work are presented in subsequent sections of this chapter. Although the use of the equations and graphs is more time consuming than the use of the computer programs, it is more cost-effective to spend the time to determine cooling passage locations before the die is constructed than to modify the die after initial production trials.

Heat Transfer Analysis

Casting and Cooling Passage Configurations Studied

Computer programs were established to model steady state heat transfer conditions in dies that produced simple

casting shapes. The casting shapes selected for analysis were a plate with finite thickness (t) but infinite width and length, and a strip with finite width (w) and finite thickness (t) but infinite length. Four cases using these simple shapes were analyzed:

- Infinite plate casting cooled by water lines.
- Infinite strip casting cooled by a single water line.
- Infinite plate casting cooled by fountains.
- Infinite strip casting cooled by fountains.

Schematic diagrams of the casting and the cooling line configurations of these four cases are shown Figs. 37–40, respectively. These casting sections and cooling passage configurations can be used in various combinations and arrangements to represent many casting and cooling passage configurations employed in commercial dies. For example, many sections and runners of frame and bezel castings are similar to the cases illustrated.

In the analysis, the effects of the following variables on the temperature distribution in the die were evaluated to determine the cooling capacities required for the selected casting sections:

1. The average die surface temperature (T_s) required to produce castings with a good surface finish.
2. Heat input $\dot{q}$, which is affected by the production rate, metal temperature, section size, latent heat of fusion, etc.
3. Thermal conductivity of the die steel (k).
4. Inlet temperature of the cooling water (T_c).
5. Flow rate of cooling water (V).
6. Distance of the water line or fountain from the die surface (L_1).
7. Distance between adjacent water lines or fountains (L_2).
8. Diameter of the water lines or fountains (D).

The results of the computer calculations were analyzed to determine relationships among the imposed

Fig. 39 Water fountain configuration used in a die section that produces a casting in the shape of an infinite plate (case 3). Only one-half of the die assembly is shown

heating and cooling conditions and the resulting die surface temperatures. Depending on the particular casting and cooling configurations under consideration, the results were correlated to provide equations (cases 1 and 2) for determining the die surface temperature as a function of the other parameters, or as a series of graphs or charts (cases 3 and 4) relating die surface temperature and the other parameters.

Results

Equations for Cases 1 and 2, Infinite-Plate and Infinite-Strip Castings Cooled by Water Lines

For case 1, the infinite state casting cooled by water lines, illustrated in Fig. 37, the average die surface temperature is expressed as:

Fig. 40 Water fountain configuration used in a die section that produces a casting section in the shape of a strip of infinite length (case 4). Only one-half of the die assembly is shown

$$T_s = \dot{q}(D \times \phi K + B(1 + L_2 / D) / 4h_c) + T_c \quad (12)$$

where T_s = die cavity surface temperature, °F (°C); $\dot{q}$ = heat input at the die surface, Btu/in.²/hr (cal/cm²/hr) [see Eqs. 15 and 16]; D = diameter of the water line, in (cm); K = thermal conductivity of the die steel, Btu/hr in. °F (cal/hr cm °C) (see Table 3); ϕ = dimensionless heat conduction parameter determined from a graph (Fig. 16) (β = dimensionless heat convection parameter determined from a graph (Fig. 16)); h_c = heat transfer coefficient between the surface of the waterline and the flowing water (coolant). This value is determined from an equation that expresses h as a function of the water properties of viscosity, density, thermal conductivity, and specific heat at the selected water temperature and pressure, and, also, of the water velocity [see Eq. 18 and Figs. 56 and 57]; L_2 = space in between water lines, in./cm; T_c = temperature of the water flowing through the water line, °F (°C).

For case 2, the infinite strip casting cooled by a single water line, illustrated in Fig. 38, the average die surface temperature can be calculated from the following equation:

$$T_s = \dot{q}(0.95)(DL_1 / K^2)^{1/2}(1 + \ln(2w + t / 3D)) + (w + t) / h_c \pi D + T_c \quad (13)$$

where T_s , q , D , k , h_c , and T_c are defined as in Eq. 12. L_1 = distance between the die cavity surface and the top of the water line, in. (cm); w = width of the casting, inches (cm); and t = thickness of the casting, in. (cm).

Equation 13 can be rearranged to solve for the distance between the die surface and the top of the water line, L_1 :

$$L_1 = k^2 / D(((T_s - T_c) / \dot{q}_s - (w + t)h_c \pi D) / (0.95)1 + \ln(2w + t))^2 \quad (14)$$

The mathematics involved in solving the equations for locating water lines is somewhat complex and lengthy. Thus the designer must spend a considerable amount of

time to solve them. Therefore to facilitate the use of this information, computer programs have been written for cases 1 and 2.^[9,10] These programs are available from the North American Die Casting Association to die casters and die designers. With the use of these programs the water line placement calculations can be performed in a matter of minutes.

Because all users of this manual may not have these computer programs, Eqs. 12 and 13 were solved for a number of conditions and the results were plotted to provide die designers with guidelines in locating water lines and dies. These graphs are presented in the next section.

Graphical Solutions of Eqs. 12 and 13^a

To aid the designer in using the results of the heat transfer analysis for locating water lines in die casting dies, the equations for cases 1 and 2 [Eqs. 12 and 13, respectively] have been solved for various casting sizes and various locations of water lines, and the results are presented in graphical form.

Case 1: Infinite Plate Castings Cooled by Water Line

The results of the computer analyses for die that employ 7/16 and 3/8 in. (11.1 and 9.5 mm) diameter cooling lines (the most commonly used sizes in the United States) to produce castings or casting sections can be approximated by an infinite plate or plotted in Figs. 41 and 42, respectively. In those figures, the distance between adjacent water lines (L_2) is plotted as a function of the heat input to the die cavity surface (q) for specific distances (L_1) of the water line below the cavity surface. The ends of each line on the graph represent the range of distances between the water lines that will result in a temperature difference across the die cavity surface of less than 20°F (11°C). The curves were determined for dies manufactured from P-20 steel. If a steel with a different thermal conductivity is used, the cooling capacity of the die would be increased or decreased by less than the percentage that the thermal conductivity of that steel exceeds or is less than, respectively the thermal conductivity of the P-20 steel used in calculation the curves. For example, the thermal conductivity of H-13 steel is about 14% lower than that of P-20 steel; however calculations using the value of k for H-13 steel shown that the die surface temperature for a given heat input and water line spacing is increased by 10% as compared with the die surface temperature obtained with the P-20 steel. Thus to use the graphs when a steel other than P-20 is used, a conservative approach would be to assume that the die

^aIn the graphs, the water line diameter D , casting thickness and width (t and w), and water line spacings (L_1 and L_2) are expressed in mm, whereas those parameters were expressed in cm in Eqs. 12 and 13.

Fig. 41 Graphs for determining the locations of 11.1 mm (7/16 in.) diameter water lines to maintain the die-cavity surface at the indicated temperatures for castings that can be approximated by a flat plate

Fig. 42 Graphs for determining the locations of 14.7 mm (3/16 in.) diameter water lines to maintain the die-cavity surface at the indicated temperatures for castings that can be approximated by a flat plate

surface temperature for each graph would be increased or decreased by the percentage by which the k value of the steel used in less than or greater than that of the P-20 steel, respectively. Thus if H-13 steel were used, the die surface temperature that would be maintained for Fig. 41 would be 570°F (296°C) rather than 500°F (260°C) because its k value is 14% lower than that of P-20 steel. Because the objective of the analysis is to insure that the die has adequate cooling capacity, using that approach will tend to assure that more than enough cooling capacity is installed in the die. Then, the desired surface temperature can be obtained and maintained by the use of commercially available die temperature control systems.

The curves presented in Figs. 41 and 42 were determined for cooling water temperature of 100°F (37.8°C). If, in practice, the cooling water temperature is different from that value, the average die surface temperature that can be maintained will be higher or lower than the value listed by approximately the amount that the actual water temperature used exceeds or falls below 100°F (37.8°C), except at very low coolant flow rates. For example, if the temperature of the coolant water flowing through the die is only 80°F (26.7°C), then the water line configurations based on Fig. 41 would be capable of maintaining the die surface temperature at 480°F (249°C) rather than 500°F (260°C). The water flow rates represented by these graphs

is 2.4 gal/min (0.15 L/sec) for the 7/16 in. (11.1 mm) diameter water lines and 4.1 gal/min (0.26 L/sec) for the 3/7/64 in. (14.7 mm) diameter water line. Higher flow rates will not significantly increase the cooling capacity of the die. If the flow rate were to become infinitely large, the increase in the cooling capacity would be about 15%. However, lower water flow rates will decrease the cooling capacity; for example, a flow rate of 1 gal/min (0.06 L/sec) will reduce for most cases the cooling capacity of the die with 7/16 in. (11.1 mm) lines by about 15% or less than that indicated by the graphs. For a die with 3/7/64 in. (14.7 mm) diameter water lines, the same flow rate will reduce the cooling capacity by about 20% or less than that indicated by the graphs.

Case 2: Infinite Strip Casting Cooling by a Single Water Line

The graphs for case 2, the infinite strip casting cooled by a single water line, are plotted in Figs. 43–45. In these graphs, the distance of the water line below the die cavity surface is plotted as a function of the heat input to one die

half, q . Figure 43 is for a 0.24 in. (6.4 mm) thick strip. Figure 44 is for 0.5 in. (12.7 mm) thick strip and Fig. 45 is for 0.75 in. (19 mm) thick strip. Each figure includes curves for two specific die temperatures, 400°F (204°C) and 350°F (177°C). The effects of variations in die material, water temperature, and flow rate would be essentially the same as for case 1 discussed earlier.

Infinite Plate and Infinite Strip Castings Cooled by Fountains

The casting in the fountain configurations for cases 3 and 4 were illustrated in Figs. 39 and 40, respectively. The results of the heat transfer analysis of the infinite plate (case 3) are given in Figs. 46 and 47 and those for the infinite strip (Case 4) are given in Figs. 48–51. The graphs were prepared for a single fountain diameter, 7/16 in. (11.1 mm), and for a fixed value of the temperature of the water flowing through the fountains, 100°F (37.7°C). The data are plotted to show heat input, q , vs. the spacing between fountain centerlines, L_2 . In Figs. 46 and 47, for the infinite plate, each cross-hatched area on the graph represents a

Fig. 43 Graphs for determining the location of 11.1 mm (7/16 in.) diameter water lines to maintain the die surface at the indicated temperatures for a casting that can be approximated by a flat strip with a thickness of 6.4 mm (1/4 in.)

Fig. 44 Graphs for determining the locations of 11.1 mm (7/16 in.) diameter water line to maintain the die surface at the indicated temperatures for castings that can be approximated by a flat strip with a thickness of 12.7 mm (0.5 in.)

particular fountain depth below the die/cavity surface. The graphs for the infinite strip have separate areas for different die thicknesses, t , and widths, w .

The cooling water flow rates were selected based on calculations that employed a wide ranges of values for the heat transfer coefficient between the water and fountain surfaces, including the use of values for the fountain interior top surface different from those used for the fountain side walls. The results for the various flow combinations are presented in the graphs in terms of flow rates that reliably provide the cooling necessary to maintain die surface temperature, T_s , as either 500°F (260°C) or 400°F (204°C). The band of cooling conditions is bounded on the upper side by a maximum or medium cooling water flow rate and on the lower side by a minimum flow rate. The flow rate corresponding to maximum cooling is 10 gal/min (0.63 L/sec), the medium rate is 4 gal/min (0.25 L/sec), and the low rate is 1 gal/min (0.063 L/sec). In practice, most cooling water flow rates are expected to be near the low end of the range, 1–2 gal/min (0.063–0.126 L/sec). On the graphs for

the strip casting with the fountains located 1 in. (25.4 mm) below the cavity surface (Figs. 49 and 50), the case for the casting 0.25 in. (6.4 mm) thick by 1 in. (25.4 mm) wide is represented by a single line for the low coolant flow rate. For higher water flow rates with that strip cross section, the temperature gradients on the die cavity surface exceeded 50°F (27.8°C).

For a fixed fountain spacing, the 500°F (260°C) or 400°F (204°C) die surface temperature, T_s , can be maintained by varying the coolant flow rate so that the rate of heat extraction equals the heat input, q , corresponding to a desired casting production rate and casting thickness. The value of q must be between the values corresponding to the two bounding coolant flow rates. The basic procedure is one minor adjustment in balancing the heat input (production rate for a particular casting) and the cooling water flow rate within the baths for a particular casting. The die designer is aided by the use of these graphs in that he can select fountain spacing and know that he can maintain the required die surface temperature for a given

production rate—he need only vary the cooling water flow rate, for example, by a temperature controller, or vary the production rate over a very small range.

General Procedures for Designing the Die Cooling System

To use the equations, computer programs, and graphs that had been developed, the designer must divide the casting into segments with shapes that are equivalent to flat plates or strips. For example, many frame and bezel castings

consist of combinations of flat plates and strips, and the runners in most castings can be considered as a strip. If the portion of the casting has a reinforcing lip or rib that is somewhat thicker than the remainder of the casting, then it is suggested that the average thickness of the section be used in the calculations. If there is a large boss present, a fountain may have to be placed immediately below the boss to ensure adequate cooling of that region. Possible cooling passage arrangements for a large shallow boss and a large deep boss on thin plate castings are illustrated in Figs. 52 and 53, respectively. The important point is that adequate

Fig. 50 Graph for determining the spacing between 11.1 mm (7/16 in.) diameter fountains located 50.8 mm (2 in.) below the die-cavity surface to maintain die-cavity surface temperature at 204°C (400°F), for castings that can be approximated by a strip

Fig. 51 Graph for determining the spacing between 11.1 mm (7/16 in.) diameter fountains located 50.8 mm (2 in.) below the die-cavity surface to maintain die-cavity surface temperature at 260°C (500°F), for castings that can be approximated by a strip

cooling capacity must be designed into the die. Thus, for a given case, one should assume the worse conditions when considering the die cooling capacity required. With sufficient cooling capacity, an automatic die temperature controller will be capable of maintaining the proper die temperature in the various regions of the die by regulating the flow of coolant.

In addition, the die designer should obtain values or reasonable estimates of the values for the various input parameters that will be fixed or restricted to a narrow range by other design or die construction considerations, or by production conditions. For example, typical water line diameters (tap drill sizes) used in the United States are 7/16 in. (11.1 mm)

and 37/64 in. (14.7 mm). Also, the temperature and velocity of the cooling water may be restricted by the temperature of the supply and the water system pressure. However, the values of these parameters should be measured at the point where the water enters the die. The flow rate can be determined by measuring the volume of flow in 1 min. Usually, these flow rates are less than 2.5 gal/min (0.16 L/sec).

Once the casting is divided into appropriate sections that can be approximated by plates and strips, the die designer must select values for the various parameters and solve the equations for T_s or locate the proper positions on the graphs. These parameters include the production rate, P , the thickness, t , or the thickness and width (t and w) of the casting

Fig. 52 Possible method for using fountains to provide cooling for a large, shallow boss on a thin plate casting

Fig. 53 Possible fountain configuration for cooling a large deep boss on a thin-plate casting. For this case, the fountains should be treated as water lines cooling a strip casting

section, the water line or fountain diameter, D , the distance between the water lines or fountains in the die cavity surface, L_1 , the spacing between water lines or fountains, L_2 , the temperature of the water in the cooling passage, T_c , and the flow rate of the water through these passages.

The value of the heat input, q , can then be determined from the casting geometry and the selected production rate as is illustrated in “Determining Input Values for Water Line Placement Calculations” section using Eqs. 16 and 17 or Fig. 54.

With the value of q and the cooling passage configuration, the designer can determine from the appropriate graph the cooling passage spacing that will maintain the

die at the desired temperature. If the desired value of T_s cannot be achieved with the initial values selected for the parameters, the die designer can repeat the procedure using different values for some of the parameters until the desired value for T_s is achieved. This procedure will allow the die designer to determine appropriate combinations of cooling passage spacings and diameters that will result in desired die surface temperature for specific values of production rate, casting section configuration, cooling water flow rate, and water temperature.

Example Calculations Using the Information Developed

To illustrate how the information developed can be utilized, sample calculations have been prepared. Assume that the die caster is producing a flat plate-type zinc die casting 0.06 in. (1.52 mm) thick, and the casting is fed by a runner 0.5 in. (12.7 mm) thick and 0.75 in. (19 mm) wide. Assume that the water line or fountain arrangements illustrated in Figs. 37–40 will be used to cool the die. The production conditions for this hypothetical casting are listed in Table 1.

Plate Casting Cooled by Water Lines

The assumed cooling system configuration shown in Fig. 37 and the assumed casting conditions (Figs. 41 and 42) are used to determine the water line diameters and spacings. Assume that the die designer elects to use 7.16 in. (11.1 mm) diameter water lines that are distance L_1 of 1.75 in. (45 mm) beneath the die cavity surface and a distance L_2 of 3.5 in. (89 mm) apart. For $t = 0.06$ in. (1.52 mm) and $P = 300$ shots per hour, Fig. 16 shows that $q = 5460$ cal/cm² hr. Using Fig. 41, the values of L_1 and L_2 for this case, and the heat input, it can be seen that the selected water line configuration can maintain the die surface at a temperature below 400°F (204°C). Thus the water line size and location selected will provide more than enough cooling capacity to hold the die surface temperature T_s at the desired temperature, 500°F (260°C). In addition, because scale may build up in the water lines and thus reduce heat transfer, the water line configurations determined in this example provide an extra margin of safety. The die temperature control system will regulate the flow of coolant to maintain the required die temperature.

Figure 38 illustrates the basic casting water line configuration for the runner feeding this casting, assuming that a single water line is used for cooling the runner. For the geometry $w/wt/(w+t) = 0.3$ in. (7.62 mm) and the desired production rate $P = 300$ shots per hour, Fig. 16 shows that $q = 700$ Btu/in²/hr (27,300 cal/cm²/hr). Should the die designer elect to place the water line 7/8 in. (22 mm) below the runner cavity surface, a check of Fig. 44 would reveal that a portion of the die around the runners does not have sufficient cooling capacity to bring the die

Fig. 54 Graph for determining the heat input, q , for each die half assuming $T_1 - T_0 = 111^\circ\text{C}$ (200°F). Graph is for Zinc Alloy No. 3. P = shots per hour; T_1 = temperature of the zinc at injection = 426°C (800°F); T_e = temperature of the casting at ejection = 316°C (600°F). The metric scale for casting thickness and the casting thickness and width parameter is expressed in millimeters whereas those parameters were expressed in centimeters in Eqs. 15 and 16

surface temperature in that region to the desired value of 400°F (204°C). Thus the die designer could elect to place the water line closer to the cavity or increase the water line diameter. Alternatively, the production rate would have to be lower to reduce the heat input at the die cavity surface.

Plate Casting Cooled by Fountains

Under the assumed casting conditions, $q = 140 \text{ Btu/in}^2/\text{hr}$ ($5460 \text{ cal/cm}^2/\text{hr}$). Figure 47, the appropriate graph for this condition, shows that fountains located 2 in. (51 mm) below the cavity surface (L_1) and 4 in. (102 mm) apart (L_2) will maintain the die surface at 500°F (260°C). To provide added cooling margin, because the cooling efficiency will decrease as scale forms in the water line, Fig. 46 can

be used to determine the cooling line spacing that will maintain the die surface at 400°F (204°C). From Fig. 47, $L_1 = 2 \text{ in.}$ (51 mm) and $L_2 = 2.85 \text{ in.}$ (72 mm).

Strip Casting Cooled by Fountains

For the assumed geometry and casting conditions, $q = 700 \text{ Btu/in}^2/\text{hr}$ ($27,300 \text{ cal/cm}^2/\text{hr}$). As was previously indicated, the desired casting surface temperature for the runner is 400°F (204°C). Inspection of Figs. 48 and 50, the appropriate graphs for maintaining the die surface temperature at 400°F (204°C), shows that for the cooling water flow rate available with the 7/16 in. (11.1 mm) diameter fountains and within the limits of the graph, fountains cannot be used to maintain the desired die surface temperature and still maintain a surface temperature variation

of less than 50°F (27.8°C). To maintain the die surface temperature at 400°F (204°C) in the runner area, the production rate would have to be decreased so that the heat input q is around 500 Btu/in.²/hr (19,500 cal/cm²/hr); that value is obtained from Fig. 48 using a 1 in. (25.4 mm) fountain spacing beneath the die surface (L_1), the minimum spacing between fountains of 1 in. (25.4 mm), and taking the lower boundary of the cooling water flow rate for the strip size under consideration. Also, $t = 0.5$ in. (12.7 mm) and $w = 3/4$ in. (19 mm). For the assumed configuration of the runner, $wt/(w+t) = 0.3$ in. (7.62 mm), the heat input value of 500 Btu/in.²/hr (19,500 cal/cm²/hr) corresponds to a production rate of $P = 200$ shots per hour (see Fig. 41).

Accuracy of the Procedure for Determining the Cooling Capacity of Dies

The procedures developed were designed to provide the die caster with a relatively quick and easy way to determine the approximate location of water lines and fountains in the dies that produce castings with configurations that could be approximated by flat plates or strips. In most cases, the procedures will provide estimates that are conservative; that is, more cooling capacity than is required will be installed in the dies. Dies designed with excess cooling capacity can make optimum use of automatic die temperature control systems.

DETERMINING INPUT VALUES FOR WATER LINE PLACEMENT CALCULATIONS

Heat Input

The value of the heat input, $\dot{q}$, can be determined from the casting configuration and the selected production rate using the following equations. For an infinite plate casting

$$\dot{q} = (C_p[T_i - T_e] + H_f)(t/2)XP \quad (15)$$

And for an infinite strip casting

$$\dot{q} = (C_p[T_i - T_e] + H_f)(wtP) / (2[w + t]) \quad (16)$$

where C_p = specific heat of the alloy being cast, cal/cm³°C (Btu/in.³°F); T_i = temperature of the metal at injection °C (°F); T_e = temperature of the casting at ejection °C (°F); H_f = latent heat effusion for the alloy being cast, cal/cm³ (Btu/in.³); t = casting thickness cm (in.); w = casting width, cm (in.); P = production rate, shots per hour.

Values of the specific heat C_p and latent heat effusion H_f for zinc Alloy 3 are listed in Table 2.

In Eqs. 15 and 16, the casting thickness or the width and thickness parameters are divided by 2 because it was assumed in the calculations that half of the total heat flux would be removed by each die half, i.e., the cover and

Table 1 Production conditions for hypothetical casting considered in the example calculations

Parameter	Value

ejector die halves. The graph presented in Fig. 54 was prepared to simplify the calculation of. In this graph, the value of is given for different combinations of casting thicknesses (or casting thickness and width) and production rate, assuming that the temperature difference ($T_i - T_e$) is 111°C (200°F). This graph can be used for both of the casting shapes considered, the infinite plate and the infinite strip, by using the proper geometry factor, t or $(w+t)/wt$, respectively.

Thermal Conductivity of Die Steel

The thermal conductivities, k , of P-20 and H-13 die steels in the temperature range of 300–500°F (149–260°C) are

Fig. 55 Graph for determining the value of ϕ and β in Eq. 12. The horizontal lines at the ends of each L_1/D curve indicate the upper and lower bounds of L_2/D for which the curves should be used and still maintain a thermal gradient on the die surface between water lines of about 11°C (20°F) or less

Fig. 56 Graph for determining h_c at low water velocities and for a 11.1 mm (7/16 in.) diameter cooling line. $D_H = 0.0365$ ft or 0.0111 m. For this water-line size, a velocity of 1 m/sec (3.28 ft/sec) equals a flow rate of 0.097 L/sec (1.54 gpm)

listed in Table 3. Single values of k are listed for the temperature range because the data indicate relatively little change in k over that temperature range.

Values for ϕ and β [For Use in Eq. 12]

The values for ϕ and β are determined from the graph presented in Fig. 55. To determine ϕ , the designer locates the value of L_2/D on the ordinate. Using the left side of the graph, a line, parallel to the abscissa, is drawn from the L_2/D value until it intersects a line that represents the value of L_1/D calculated by the designer. A line is drawn from the intersection point on the L_1/D line perpendicular to the abscissa, and then the value of ϕ is read. The value of β is determined in exactly the same manner, except the right side of the graph presented in Fig. 55 is used. In Fig. 55, the short, horizontal lines drawn at the ends of the L_1/D curves indicate the upper and lower bounds of L_2/D for which the curves should be used and still maintain a

thermal gradient of 11°C (20°F) or less on the die surface between the waterlines.

The values of h_c can be determined from the following general equation:

$$h_c = CXk_{T_c} / D_H (VD_H \rho_{T_c} / \mu_{T_c})^{0.08} \times (u_{T_c} XC_p / K_{T_c})^{0.4} \quad (17)$$

where h_c = heat transfer coefficient between the surface of the waterline and the flowing water (coolant) expressed here as cal/hr/cm²°C (Btu/hr/ft²°F); C = a constant, 9.6×10^{-4} for metric units and 2.3×10^{-2} for English units; μ_r = thermal conductivity of the water flowing through the dies at an average temperature T_c , cal/hr/cm °C (Btu/hr/ft °F); D_H = the hydraulic diameter of the cooling channel for a channel of circular cross section (tube or pipe), D_H is equal to the inside diameter of the channel, m (ft); V = velocity of water through the cooling channel, m/sec (ft/hr); ρ_{T_c} = density of the flowing water taken at some average temperature T_c , kg/m³ (lb/ft³); μ_{T_c} = absolute viscosity of water

Fig. 57 Graph for determining h_c at low water velocities and for a 14.7 mm (37/64 in.) diameter cooling line $D_H = 0.0482$ ft of 0.0147 m. For this water-line size, a velocity of 1 m/sec (3.28 ft/sec) equals a flow rate of 0.169 L/sec (2.69 gpm)

taken at some average temperature, kg/m/sec. (lbs./ft./hr); C_p = specific heat of water at some average temperature, T_c , cal/kg °C (Btu/lb °F).

The English unit of h_c as calculated by Eq. 17 is Btu/hr/ft²°F. This value must be divided by 144 to convert it to the proper units of h_c for use in Eqs. 12 and 13, i.e., Btu/hr/in.²°F. The average water temperature T_c at which the various physical properties of water are determined is taken as the arithmetic mean of the inlet and exit water temperatures of the dies. To simplify the determination of h_c , the graphs presented in Figs. 56 and 57 were prepared for typical values of cooling line diameter, D_H , water velocity, V , and average temperature, T_c . In these curves, all necessary conversion factors have been used to provide the value of h_c with the proper units for use directly in Eqs. 12 and 13.

Value of Water Temperature T_c

As was previously indicated, T_c is the average of the inlet and exit temperatures of the water flowing through the water lines in the die. Based on information obtained from field investigations, die casters typically run water through their dies so that sufficiently high velocity that usually there is a difference of less than 5°C (10°F) between the inlet and outlet water temperatures. Thus for practical purposes, T_c can be set equal to the inlet water temperature.

Abstract

The Diesel engine, introduced by Rudolph Diesel in 1892, achieves a higher combustion ratio and fuel efficiency, has lower CO₂ emissions per mile than the gasoline engine and is considered to be one of the most viable environmentally friendly technologies for vehicles. “Clean Diesel” using lower sulfur content fuel has become available since 2006. Currently, the Diesel engine and cylinder head are mostly cast iron to withstand the high compression pressures and temperatures of Diesel operation. Further weight reduction (40%–55%) via aluminum substitution in the Diesel engine would result in substantial fuel economy and increased environmental benefits. Current aluminum alloys cannot meet the requirements of the Diesel engine and a new research topic has emerged in aluminum materials technology to address these requirements. The main issue with aluminum alloys is the low resistance to thermal fatigue that results from the constrained expansion and contraction of the material in the interval regions leading to compressive creep deformation at 300°C during engine heat-up and to tensile deformation around 150°C during engine cooldown. This article discusses the performance requirements and the design principles for aluminum alloys for Diesel engine applications. Efforts on the modification of A356 and A319 alloys via Cu, Mg, Ni, Cr, V, Zr, Ti, and Mn addition are reviewed. Recent studies on Mn/Mo addition are presented and the related principles are introduced in designing high volume fraction, thermally stable, and uniform nanoscale dispersoids using solutes with opposite partitioning coefficients in aluminum.

Keywords: Aluminum alloys; Creep resistance; Diesel engine applications; Mo-Mn alloying; Nano-precipitates; Thermal fatigue.

INTRODUCTION

Aluminum usage in engine applications started in the early 1980s. Today, gasoline engines are commonly made of high-temperature aluminum alloys; however, the use of aluminum in Diesel engines that operate under severe stress and temperature conditions is limited. The Diesel engine, introduced by Rudolph Diesel in 1892, achieves self-ignition via fuel injection into air which is already compressed in the combustion chamber. Compared to gasoline engines (Table 1), the Diesel achieves a higher combustion ratio and fuel efficiency.^[1,2] The Diesel has lower CO₂ emissions per mile than the gasoline engine and is considered one of the most viable environmentally friendly technologies for vehicles. Market penetration of the Diesel in Europe shows substantial growth

since 1991 reaching 50% (70% in France) market share; while in North America, it sees slow acceptance (1% cars and 4% light trucks) due to past experience with older technologies and sulfur-containing fuel (Fig. 1a). However, “Clean Diesel” using lower sulfur content fuel has become available since 2006.^[3] Currently, the Diesel engine and cylinder head are mostly cast iron to withstand the high compression pressures and temperatures occurring in Diesel operation (Table 1).

Further weight reduction via Al substitution in the Diesel engine would result in substantial fuel economy and increased environmental benefits. Substituting cast iron block with aluminum would result in 40%–55% weight reduction of the Diesel engine. In Fig. 1b, the material properties of compacted graphite iron (CGI), cast iron, and an aluminum alloy are compared. The low

Fig. 1 (a) Market use of Diesel engines.^[3] (b) Comparative properties of CGI, gray iron, and AlSi9Cu^[4]

density and the modulus of elasticity, and high thermal conductivity make aluminum an attractive candidate. The main shortcomings of the commercial aluminum alloys are the loss of strength and creep resistance with temperature, which have limited their use in Diesel engine components. The peak firing pressure for aluminum Diesel engines is set to below 170 bar for inline and 150 bar for V engines.^[4] Efforts in converting Diesel engine from cast iron to Al alloys have started in 1996. VAW (Germany)^[4–5]

and Alcan-Pechiney (Canada, France)^[5] have initiated Al Diesel alloy development. Presently, only a small portion of the Diesel engines, mainly the cylinder head, is cast in aluminum and certain experimental alloys exist.^[4–8] However, increasing torque requirements in newer Diesel engines that are mostly common, rail turbo Diesels necessitate new alloys with improved performance under thermal fatigue conditions. Current Al alloys cannot meet the requirements of the Diesel engine, and a new research topic has emerged in aluminum materials technology to address these requirements.

Table 1 Gasoline vs. diesel engines^[1, 2]

	Gasoline engine	Diesel engine
Combustion cycle	Four stroke	Four stroke
Ignition type	Spark	Self
Combustion ratio	10:1	20:1
Fuel and average energy per gallon		
CO ₂ emission/mlle	19.4 lbs	13.4 lbs
Compression pressure and temperature	100 MPa and 175°C	150 MPa and 300°C

THEORETICAL BACKGROUND

From a material point of view, the important components of the Diesel engine are the engine block, the cylinder head, and the pistons. Of the two candidates for Al conversion (engine block and cylinder head, Fig. 2a,b), the cylinder head (Fig. 2b) has severe operating conditions due to thermal fatigue (also called thermomechanical fatigue) in the inter-cylinder bridge (Fig. 2c) and requires improved alloys.^[6,9–14] The cylinder head is subjected to two modes of

Fig. 2 (a) Engine block, (b) cylinder head, and (c) thermal fatigue cracks in an A319 cylinder head, the circles indicate the inter-valve regions between where cracks occur^[8]

fatigue: (i) mechanical fatigue near the water ducts and (ii) thermal fatigue in the combustion chamber.

Mechanical fatigue results from the rotation speed of the engine and causes cracks in the moderately warm areas. Thin walls (~10 mm) in proximity to the water ducts are critical locations for the mechanical fatigue-crack initiation. Temperature in these regions can be in the range of 120°C–170°C.^[9] The intrinsic fatigue strength of the alloy as well as the casting conditions (local porosity, secondary dendrite arm spacing (SDAS), and the morphology of the intermetallic compounds) and residual stresses influence thermomechanical fatigue performance.^[15]

In order to determine the performance requirements of Diesel cylinder head alloys, thermal fatigue needs to be understood. *Thermal fatigue* is more complicated to analyze. It occurs in the inter-cylinder (inter-valve) bridges (Fig. 2c) and is related to the heating and cooling cycles of the engine. It has been reported that the damage caused by thermal fatigue is more severe than mechanical fatigue and determines the lifetime of the engine components.^[5] The thermal stresses developed during engine operation and related damage mechanisms are shown in Fig. 3a. Limited information exists on actual stress measurements during Diesel operation because of the inherent difficulties in measuring stress fields near critical regions, but a number of studies on modeling and predicting thermo-mechanical fatigue (via finite element method) in engine components have been conducted.^[17–20] Thermal fatigue cracks can be nucleated during the engine cooldown period if the initial creep deformation is high, and the

material does not have sufficient ductility to accommodate these stresses by local plastic deformations. Even when the material is ductile, the repetition of these alternating compressive and tensile stresses (also called thermal fatigue) can cause crack initiation due to plastic damage accumulation and eventually lead to failure in Diesel engines.

The mechanism proposed for thermal fatigue in 1988 is still accepted:^[5]

- At maximum load, the inter-cylinder zone reaches 300°C near the combustion chamber surface while the interior remains at the ambient temperature (sometimes as low as –30°C). The thermal expansion is prevented by the rigidity of the cylinder head (especially if flat surfaced) and the local compressive stress causes creep deformation (Fig. 3b).
- At engine cooldown, the inter-cylinder contraction is constrained by the adjacent zones that do not contract to the same degree. As a consequence, a tensile stress is set.
- The repetition of this cycle causes fatigue-crack initiation at or near the combustion chamber surface in low-cycle fatigue (LCF) mode. Cracks can eventually propagate and lead to failure. It is noteworthy that the stresses generated are more severe immediately after engine start-up and become less significant as the steady-state condition establishes. Because of the compressive nature of the stress field, the creep deformation does not cause crack generation during engine operation.^[21,22]

Fig. 3 (a) Temperature distribution in an inline Diesel engine, hot spots can be seen between the combustion chambers.^[16] (b) Thermo-mechanical stresses and damage mechanisms during engine start–stop cycle

There is no real intrinsic material property that can be considered to be *thermal fatigue resistance*. Clearly, resistance to creep at 300°C would be beneficial for the full load condition. However, as the temperature starts to decrease from 300°C at engine cooldown, tensile conditions that set up require either elastic accommodation of the tensile stress (high yield strength) or plastic accommodation (high ductility). A combination of these three properties (strength, creep, and ductility) would improve the thermal fatigue performance of the alloy in a Diesel engine.

Previous results indicate that intrinsic mechanical fatigue strength of the material does not correlate with thermal fatigue resistance.^[5] Interestingly, the tendency for thermal fatigue failure has been related in steel to the parameter:^[23]

$$R_{TS} = \frac{\sigma_f k}{E \alpha} \quad (1)$$

Here, σ_f is the mechanical fatigue strength at mean temperature, k is thermal conductivity, E is the modulus of elasticity, and α is the coefficient of thermal expansion. Generally, alloys with high thermal conductivity, low modulus of elasticity, and low coefficient of thermal expansion are favorable for thermal shock resistance. No study on this relationship, however, exists in Al.

Based on the foregoing explanations, the material property requirements for Al Diesel engine alloys are as follows:

- *Compressive creep resistance* at up to 300°C to resist creep deformation in the inter-valve regions during engine heat-up.
- *Ductility* to accommodate the tensile stresses either elastically or plastically during engine cooldown and avoid catastrophic failure.
- *Strength* to accommodate the tensile stresses elastically when ductility is low.

It is usually difficult to attain all three requirements when developing an alloy. While there is not real discussion on the relative importance of these properties, it seems that certain researchers have considered tensile strength to be a key property and have therefore based on their alloy development efforts on Al-Si-Cu alloys that are known to have higher strength than the Al-Si-Mg alloys. However, there have also been attempts to optimize alloys based on the Al-Si-Mg system, which is known for lower strength but higher ductility than the Al-Si-Cu alloy. In view of the mechanisms of crack formation, it can be considered that tensile ductility can be more important than the tensile yield strength because plastic deformation would delay crack nucleation and propagation.

Recently, Wong and Mai et al.,^[24] by including the creep damage in the Coffin–Manson fatigue equation, have shown that in creep–fatigue situation (i.e., thermal fatigue), at low cycle times or low temperatures, pure fatigue is the dominant damage mechanism, and as the cycle time or temperature increases, creep becomes significant (Fig. 4). Ultimately, at high temperatures or long cycle times, pure creep is the dominant damage mechanism. On the basis of these analyses, because of the relatively long start–stop cycle time and high temperature of engines, *creep* can be considered to be more critical than fatigue in the inter-valve regions.

Among other performance requirements for Diesel alloys, a sound solidification structure, good castability, quench sensitivity, thermal stability of age-hardened structures, high thermal conductivity, and cost effectiveness can be sighted. The castability and solidification structures of Al Diesel engine alloys have been evaluated via SDAS, porosity evaluation, and hot-tearing. A fine SDAS in the range of 15–30 μm is desired. The alloy also has to possess good castability, cost-effectiveness, availability, and recyclability.

Fig. 4 Change of mechanism with cycle time and temperature^[24]

Alloy Design for Aluminum Diesel Cylinder Head Alloy

The challenge in aluminum alloy design for Diesel cylinder heads seems to lie in obtaining a good combination of elevated temperature strength, ductility and creep resistance (up to 300°C), and low propensity for crack initiation or propagation, all of which will ensure acceptable thermal fatigue performance.

Elevated Temperature Strength and Ductility

Pure aluminum can be strengthened up to twice the yield strength (σ_y) by solid solution strengthening, up to $9\sigma_y$ by dispersoid strengthening, and up to $30\sigma_y$ by age (precipitate) hardening. Effectiveness of *age hardening* depends on alloy system, Mg-Zn-Mg-Cu achieving highest strengths with the η' -MgZn₂ precipitate. For good castability, Al casting alloys are based on the Al-Si system and depending on the additional Mg and/or Cu content can have the low strength (β' -Mg₂Si, λ -Al-Mg-Si-Cu) or the precipitation sequence of the higher strength phases (θ -AlCu, Q-Mg-Si-Cu). Age-hardened alloys at peak strength have metastable precipitates (T6), low fatigue ratio, and often low ductility. However, age hardening is mostly lost during elevated temperature exposure. The T6 alloys soften at precipitate aging (transformation of metastable phases to equilibrium phases and precipitate coarsening) result in loss of strength with some gain in ductility. At 10,000 h of exposure, significant softening is inevitable. The Diesel engine being subjected to repeated exposures to elevated temperatures (as high as 300°C) would convert the T6 tempers to T7 with equilibrium precipitates. Hence, the strength of the Diesel engine alloy needs to be designed on the *overaged/equilibrium* state microstructure and the tensile properties need to be evaluated after at least 500–1000 h presoaking at temperature. Since peak age T6 is not sustainable in Al alloys for Diesel cylinder heads, the nature of the equilibrium precipitate determines the strengthening effect. In the Al-Si-Mg-Cu system, the equilibrium precipitates can vary depending on the Si/Mg ratio and Cu level. This quaternary alloy composition can be adjusted to give (Q, Si, θ) or (Q, β , Si) equilibrium phases. While the mix of equilibrium precipitates are known in wrought Al alloys with low Si levels, the precipitate mix vs. composition in experimental casting alloys of higher Si needs to be defined via thermodynamic calculations and differential scanning calorimetry validations.

- a. *Precipitate modification:* The use of trace elements is one avenue to modify the equilibrium phases and influence the strengthening. For example, small addition of Ag changes the equilibrium phase θ to ω phase with close relationship to θ but with matrix coherency^[25] resulting in high degree of strengthening. Trace

addition of Sn and Bi also influences the strengthening effect of θ' by refining the precipitate size. However, trace elements need to be selected with cost or recyclability in view.

- b. *Dispersoid strengthening:* This is a key design feature in improving the elevated strength of aluminum. It is of prime importance for Diesel engine alloys where age hardening is lost with exposure to peak temperatures during use. The degree of *elevated temperature strengthening from dispersoids* depends on the location (interdendritic vs. intradendritic), amount, size, morphology, interparticle spacing, coherency, and thermal stability. Strengthening effect of the dispersoids depends on fine dispersion with low interparticle spacing to ensure effective Orowan strengthening and on matrix coherency. Thermal stability of these phases is governed by low solid solubility and low diffusivity in Al. The rate constant of Oswald ripening is given by^[26]

$$K \approx \frac{D\gamma}{(C_e^\beta - C_e^\alpha)^2}, \quad (6)$$

where D is diffusivity of the rate-controlling solutes, γ is interfacial energy, C_e^α is the solute solubility in the Al matrix, and C_e^β is the solute concentration of the precipitate. To have a thermally stable precipitate, the constituent solute atoms must have low solid solubility and low diffusivity in the Al matrix.

Alloying with slow-diffusing solute atoms that have solid solubility in the precipitates is also known to increase the resistance to Oswald ripening. Kuehmann and Voorhees^[27] have shown that addition of a third alloying element with low diffusivity to a binary system can decrease the rate constant of Oswald ripening. When the diffusivities of the third component (D_3) and the second component (D_2) are identical (Fig. 5, $D_3 = D_2$), the rate constant decreases equally via addition of the either of the components. However, in the case where the third component has a higher diffusivity (Fig. 5, $D_3 = 10D_2$), the addition of the second component leads to a rapid decrease in the rate constant.

Importantly, a distinction can also be made between eutectic and peritectic elements. Eutectic phases form in interdendritic regions of the cast alloy, while peritectic phases will form intradendritically. Eutectic phases may strengthen the grain boundaries, while peritectic phases may provide effective obstacles to dislocation motion within the grain. So both types are needed. The majority of elements form eutectic phases with Al; among the “peritectic” elements, Zr, Ti, V, Hf, Ta, Cr, Sc, B, Co, Mn, Mo, and Ta can be cited. In multicomponent alloys, the type of dispersoid intermetallic that forms is usually ternary or quaternary, and these cannot be predicted unless thermodynamic calculations are performed. For example, in Al-Si alloys, Zr forms a ternary Al-Zr-Si intermetallic rather than the binary ZrAl.

Fig. 5 The normalized coarsening coefficient of precipitates for a dilute ideal ternary alloy, showing the effect of ternary addition. Indices 2 and 3 represent the second and the third components in the alloy system, respectively^[27]

In solid state formation of dispersoids, their amount is determined by solute supersaturation within the matrix during nonequilibrium solidification. The degree of supersaturation at a constant solidification rate mostly depends on two factors:

1. Solid solubility of solute atoms at the invariant reaction temperature (C_s)
2. Liquid solubility of solute atoms at the invariant reaction temperature (C_L)

Creep Resistance

The main creep deformation mechanism at 300°C is dislocation (climb, pipe diffusion, activated cross slip intersection, movement of solute atmospheres) creep where the vacancy generation and self-diffusion of Al is involved. Only very fine and closely spaced thermally stable dispersoids^[26] and high melting point solutes (e.g., Cu, Y, Mo, Sc) creating stable dislocation atmospheres can provide obstacle to dislocation creep. Grain boundary migration can also be active and can be prevented by thermally stable dispersoids at grain boundaries. For effective results, Oswald ripening of precipitates needs to be minimized to ensure continued creep resistance at temperature. The rate constant of Oswald ripening is proportional to where D is the diffusivity of the rate-controlling solute, γ is the precipitate-matrix interfacial energy, and C^α and C^β are the equilibrium solubility of solute in the matrix and precipitate. A low γ (low mismatch in lattice parameter) and low diffusivity would minimize coarsening. Grain boundary migration, on the other hand, can be prevented by avoiding creep-induced precipitation near grain boundaries by ensuring a thermally stable microstructure in the vicinity of grain boundaries. A coarse grain is usually desired to minimize grain boundaries (for example, Mn, a grain coarsener can be added), however, if the grain boundaries are effectively strengthened, a fine grain may not be detrimental.

Aluminum Alloy Development for Diesel Engines

Al alloys used in gasoline engines are based on the Al-Si system with Mg and/or Cu addition (A356, A319). A356 (Mg-7%Si-0.4%Mg) has good ductility and moderate strength and 319 (Al-6%Si-4%Cu) has higher strength and creep resistance than A356 at 250°C but lower ductility. A356 is used in T6 or T7 condition, and the age-hardening sequence is based on GP zones $\rightarrow \beta' \rightarrow \beta$ (Mg₂Si) giving moderate strengthening. 319 and its variants (with Si varying between 5% and 8% and sometimes containing Mg as well) are used in F or T5 condition in cylinder heads.^[5]

The Fe level affects the ductility of Al-Si alloys; usually low Fe (primary) alloys have thin-plate or rodlike β -Al₃SiFe, and if Mg is present, the polyhedral π -Al₃FeMg₃Si₅ and the high Fe alloys (secondary, recycled) will have the Chinese script α -Al₁₅(Mn, Fe)₃Si₅ and the β -Al₃SiFe. A study on the effect of increasing Fe from 0.1% to 0.5% in A356 showed that the length of the Fe intermetallics changed from 6 to 25 μ m and the amount and size of pores increased with increasing Fe. This resulted in a decrease in tensile ductility (60%) and in UTS (8%) and increased the fatigue crack-growth rate, da/dN , through its effect on the Paris exponent.^[11] Si-eutectic phase was seen to be crack-propagation path in thermal fatigue of various Al-Si alloys.^[9,13] Modification of the Si phase, e.g., via Sr, the elimination of the brittle Fe intermetallics, and the reduction of porosity would be beneficial in delaying crack initiation and in decelerating crack growth.

Cu- and Mg-Modified Alloys

Cu addition to Al-Si-Mg alloys lead to the formation of Q-Al₅Mg₈Cu₂Si₆L $\rightarrow \lambda$ (Al-Si-Cu-Mg) or the θ -CuAl₂ phase. Li et al.^[28] observed that the peak-aged hardness and the tensile strength of an A356 alloy increases with increasing the Cu content of the alloys. They attributed this outcome to the increased density of β'' and the precipitation of the precursors of the Q-Al₅Mg₈Cu₂Si₆ in the peak-aged

Fig. 6 The influence of Cu on the microstructure of the A356 alloy after T6 heat treatment: (a) A356, (b) A356+1% Cu, and (c) A356+3% Cu^[28]

condition (Fig. 6). In the alloy with 1% Cu (Fig. 6b), only Q' and β' precipitates coexist. At higher Cu content (Fig. 6c), the θ' precipitates were also observed. Cáceres and Djurdjevic et al.^[29] have studied the effect of Cu addition on the porosity level in the A356 alloys. It has been shown that Cu more than 0.2% increases the amount of microporosity significantly (Fig. 7). This is related to the significant reduction of the eutectic temperature and an increase in the solidification range.

To meet the higher performance requirements of the *Diesel cylinder head*, the initial alloy development (VAW, 1998) focused on Cu addition to A356 to increase strength and creep resistance at 200°C–250°C. Feikus^[6] has shown that Cu up to 0.5 wt% improves strength at 150°C–250°C without impairing the ambient temperature ductility, while increasing the creep time-to-fracture at 200°C, 120 MPa from 22 to 214 h. Further Cu addition had no significant influence on

strength or creep resistance but adversely affected ductility. In the VAW alloy, the Cu addition resulted in age hardening via the $L \rightarrow \lambda(\text{Al-Si-Cu-Mg})$ in addition to the GP zones $\rightarrow \beta' \rightarrow \beta(\text{Mg}_2\text{Si})$. The strength advantage is, however, lost at 300°C service temperature. When over-aged, the T7 temper of the VAW alloy maintains some ductility.^[6–7] This alloy gained a small market share in Europe but is no longer used due to increase torque pressure and temperatures in the Diesel engine. Mechanical (isothermal) and thermal (100°C–300°C) fatigue properties of A356, A356+0.5Cu, and low and high Fe versions of 319 were evaluated by Ford.^[30] No real difference was observed between the alloys with respect to LCF life prediction and thermal fatigue life. High-cycle fatigue (HCF) behavior differed, with the A356 and A356+0.5Cu showing superior HCF performance to 319 alloys. Fatigue-crack propagation was transgranular along eutectic phase boundaries.

Fig. 7 (a) Isopleth at 7%Si, 0.5%Cu, 0.1%Fe calculated via Thermo-Calc, showing the role of Mg level in phase formation in the A356+0.5Cu alloys, (b) enlargement of the boxed area in (a), θ -Al₂Cu, Q -Al₅Cu₂Mg₈Si₆, M -Mg₂Si, β -Al₅SiFe, π -Al₈Mg₃FeSi₆.^[31]

Recently, Farkoosh and Pegguleryuz have shown that^[31] in the A356+0.5Cu alloy, the θ -Al₂Cu precipitates are thermodynamically unstable at 300°C (Fig. 7a). Therefore, Q-Al₅Mg₈Cu₂Si₆ remains as the only strengthening Cu precipitate at this temperature, and because of its rapid coarsening kinetics and low amount, Orowan strengthening is insignificant for the applications that require high creep resistance and strength at this temperature. However, in a recent study,^[31] thermodynamic calculations along with experimental investigations have shown the possibility of improving the mechanical properties at 300°C by increasing the Mg level to its maximum solid solubility limit, ~0.5 wt% in this alloy system (7% Si, 0.5% Cu). The increase in strength and creep resistance with Mg is attributed to the higher amounts of the Q precipitate and the promotion of Orowan strengthening.

Increasing the Mg to the solubility limit of 0.47 wt% increased the amount of Q (Fig. 8) and improved the strength and creep resistance at 300°C.^[31] It is found that there is an optimum Mg level for obtaining maximum elevated temperature strength of the base alloy. The YS and UTS at 300°C showed ~30% and ~50% increase, respectively, when the Mg level increased from 0.3% to 0.5%. The elongation was decreased by ~20%. An order of decrease (from 10⁻⁹ to 10⁻¹⁰ s⁻¹) was seen in minimum creep rate at stresses 15–18 MPa as Mg increased from 0.3 to 0.5 wt%. However, the difference was not significant when creep stress increased to 25 MPa.

Ni-Modified Alloys

Owing to its low solid solubility and low diffusivity in Al, Ni is known to impart elevated temperature strength to aluminum alloys by forming thermally stable aluminides within the microstructure.^[33–35] Ni-containing Al-Si alloys are used extensively as engine piston alloys that require high strength at elevated temperatures.^[34] Research has been conducted to investigate the strengthening mechanisms activated by Ni addition. Ashgar and Requena et al.^[36] have proposed that, in piston alloys, Ni aluminides that form

as eutectics increase the interconnectivity of the eutectic microconstituent and provide strengthening at elevated temperatures when the aluminum matrix softens with the coarsening of the age-hardening precipitates. Stadler and Antrekowitsch et al.^[37] have also shown that the load transfer mechanism is effective even after solution treatment of different grades of Al-Si-Cu-Mg-Ni alloys.

In 2001, a *Diesel engine block* alloy was developed by VAW to meet the higher strength requirements of this component. The engine block, while requiring higher strength than the cylinder head, can sacrifice some ductility and is not as prone to thermal fatigue failure as the cylinder head.^[11] Heusler and Feikus et al.^[11] developed an alloy by adding Ni at low levels to the A356+0.5Cu alloy. The A356+0.5Cu was improved through design of experiments on Si, Mg, Fe Cu, Ni, Mn addition to give an Al-7Si-0.4Mg-0.4Cu-0.5Ni-0.4Fe alloy. Increasing the Ni content from 0.1 to 0.3 improved the strength after pre-aging, and the Ni content was thus fixed at 0.5%. The alloy tested in T6 condition yielded a high tensile strength, but it is not clear if the intermetallic phase AlFeNi may enhance creep resistance in this Al alloy.^[11] However, a loss of strength was seen when the alloy was tested after 500h of pre-aging. It is known that an intermetallic phase Al₅FeNi may enhance creep resistance in Al alloys.^[11] Mechanical fatigue evaluation showed that the Ni-containing alloy had slightly better fatigue strength than 380. This alloy showed a 20% increase in fatigue strength and improvements in tensile strength over the A356+0.5Cu alloy; however, ductility decreased because of the large amount of brittle intermetallics that formed as a result of Ni addition. Ductility at 250°C was 20% lower than A356 (45%) but higher than 319 (8%). It should be noted that the early alloy development by VAW looked at alloys with varying Fe levels.^[6,7,11]

In 2013, Farkoosh et al. conducted research on Ni addition to Al-Si-Cu-Mg alloy.^[32] Thermodynamic simulations based on the Calculation of Phase Diagrams (CALPHAD) method were used to assess phase formation in Al-7Si-(0-1) Ni-0.5Cu-0.35Mg alloys (in wt%) under equilibrium and

nonequilibrium (Scheil cooling) conditions. Calculations showed that the T-Al₃FeNi, γ -Al₇, Ni, δ Al₃, CuNi, and ϵ -Al₃Ni phases form at different Ni levels. Ni suppressed the formation of θ phase. It was determined that the Ni:Cu and Ni:Fe ratios control the precipitation which was verified via microstructural investigation of alloys (Table 2) in the as-cast, solution-treated, and aged conditions using electron probe microanalysis, scanning electron microscopy (SEM), X-ray diffraction, and transmission electron microscopy (TEM).

Table 3 shows the precipitates that form at different Ni levels and alloy conditions. TEM analyses showed that while the θ phase is absent in the as-cast condition, it precipitates along with Q and Si precipitates after aging (Fig. 9). Hardness measurements of the overaged samples showed that in this alloy system, the δ -Al₃CuNi phase has a greater influence on the overall strength of

the alloys compared to the other Ni-bearing precipitates. Experimentally, investigation was conducted on 4Al-7Si-0.5Cu-0.3Mg-(0.3-1)Ni alloys (Table 2) for elevated temperature performance. It was found that while the yield strength of the overaged alloys at 300°C increased with Ni, but the creep resistance decreased (Fig. 10a–c). Microstructural observations (Fig. 10d,e) revealed that the brittle interdendritic T-Al₃FeNi intermetallics undergo severe cracking in the early stages of creep deformation that weakens the interdendritic regions and leads to a decrease in creep resistance.

A follow-up study by Farkoosh and Pekguleryuz investigated the effect of Mn addition on Ni-containing Al-Si-Cu-Mg alloy.^[38] Mn addition (0.32 wt%), Table 4, modified the T-phase by dissolving in it (up to 2 wt%) which would improve of the phase by making it nonstoichiometric. An improvement in creep resistance was seen with Mn

Fig. 9 TEM micrographs of Al-7Si-0.5Cu-0.35Mg-0.1Fe-1.0Ni after 200°C aging. (a) θ and Q precipitates formed on the (001) plane of Al after 170 h of aging. (b) θ , (c) Q, and (d) Si precipitates after 600 h of aging^[32]

Fig. 10 (a)Tensile properties at room temperature (b) 300°C. (c) Tensile creep curves at 300°C, 20MPa; alloys aged for 600h at 200°C and soaked for 100h at the test temperature prior to testing. Mn-modified alloy shows the lowest creep strain. (d) The microstructure of the alloy MG3R10N alloy after 300h creep test at 300°C, 20MPa showing a cracked T-Al₃FeNi intermetallics. (e) In the Mo-modified alloy, the T-Al₁₉FeNi intermetallic is undamaged after creep testing at 300°C, 20MPa. The crack in the Al matrix stops at the intermetallic phase boundary

addition to the Ni-containing alloy (MG3R10N03M). The minimum creep rate decreased from $1.95 \times 10^{-7} \text{ s}^{-1}$ in the MG3R10N not containing Mn to $1.45 \times 10^{-7} \text{ s}^{-1}$ in the Mn-containing MG3R10N03M alloy (Fig. 11a). Figure 11a and b compares the T-phase in Ni-containing alloys with and without Mn addition. While the T-phase cracks after creep testing in Ni-alloys with no Mn, the T-phase in the alloy with Mn addition remains undamaged after creep testing. However, the ductility and strength do not improve with Mn addition.

Dispersoid-Strengthened Alloys

Due to loss of age-hardening strength during elevated temperature service, alternate effective strengthening

mechanisms are sought for Al Diesel engine alloys. Recent alloy development activities in high temperature Al alloys have focused on designing dispersoids in the microstructure. Dispersoids offer less strengthening effect than age-hardening precipitates unless the dispersoids are of very high volume fraction, fine and closely dispersed for effective Orowan strengthening, and thermally stable at repetitive exposure to elevated temperatures (above 250°C). The combination of these attributes is difficult to attain in aluminum because the thermal stability of the dispersoids depends on low solid solubility of the alloying addition in the aluminum matrix that gives rise to low volume fraction especially in the case of the Al-Si cast alloys.^[39] Si improves castability but lowers the peritectic and eutectic temperatures and the solid

(b) Cracked T-phase in creep-tested Ni-containing alloys with no Mn. (c) T-phase in Ni-containing alloy with Mn, it has remained undamaged after creep testing. The crack in the Al matrix was arrested at the intermetallic^[38]

solubility of the alloying elements in Al.^[6] Furthermore, Si incorporates in the structure of the dispersoids, specially trialuminides, and thereby decrease their coarsening resistance.^[11,12]

On the basis of their crystal structures, the dispersoids found in Al alloys can be categorized into two main groups of intermetallics: (i) trialuminides (Al_3M) with cubic L_{12} or tetragonal D_{022} and D_{023} structures (e.g., Al_3Sc , Al_3Zr , Al_3Hf , and Al_3Er) and (ii) quasicrystals or their approximants (e.g., AlMnSi and AlCrSi). Trialuminides are known to be coherent dispersoids, because of possessing crystal structures similar to Al.^[40–46] Quasicrystals and their approximants, on the other hand, are generally believed to form incoherent precipitates/dispersoid with low strengthening efficiency. These dispersoids are commonly formed through addition of alloying elements such as Cr and Mn. Single addition of Cr forms a face-centered cubic (FCC) $\alpha\text{-AlCrSi}$ dispersoid phase ($a_0 = 10.9 \text{ \AA}$); these dispersoids have an incoherent or semicoherent interface with the Al matrix, and the strengthening efficiency is low.^[6] Mn addition, single or in combination with Cr, forms Mn- and/or Cr-containing dispersoids referred to as $\alpha\text{-Al(Mn, Cr, Fe)Si}$ intermetallics.^[13,14] The crystal structure of this phase is simple cubic (SC) or body-centered cubic (BCC) depending on the chemical composition (Mn:Fe ratio and the presence of trace elements such as B) and has a large lattice parameter, a_0 in the range of 12.5–12.7 $\text{\AA}$. Recently, Li and Brusethaug et al.^[28] have shown that in an Al-Mn-Si-Fe system, it is possible to achieve significant dispersoid strengthening by precipitation of partially coherent $\alpha\text{-Al(Mn, Fe)Si}$ approximant phase. One-dimensional coherency between the (235) planes of the dispersoids and the {020} planes of the matrix was reported.

Zr-, Mn-, V-, and Cr-Modified Alloys

Low ductility of the A319 (Al-7Si-4Cu) alloy has limited its use for Diesel engine applications despite the higher strength and creep resistance of these alloys compared to the A356 alloy family (Table 5). Improving the ductility of A319 alloys was one of the primary alloy development routes for Diesel engine applications. The second generation of the engine alloys was developed by Rio Tinto Alcan (France)^[5] via Zr and Mn modification of the A356+0.5Cu alloy. V, Zr, and Ti are peritectic elements added as stable dispersoid-formers to improve the creep resistance of the alloy. Garat et al.^[5] formulated a new Al-7Si-(3–4)Cu alloy with lower amounts of Fe content ($\sim 0.1\%$) for improved ductility and low addition of Zr (0.15%), V (0.25%), and Mn (0.15%) for strength. Mg was suppressed to eliminate the low-temperature (525°C) quaternary eutectic allowing higher solutionizing temperature and to improve ductility. Exclusion of Mg changed the aging sequence from $\beta\text{-(Mg}_2\text{Si)}$ and $\lambda\text{-(Al-Mg-Si-Cu)}$ to the well-known GP zones $\rightarrow \theta'' \rightarrow \theta' \rightarrow \theta$ (Al_2Cu) precipitation yielding higher precipitate stability. A ternary Al-Si-Zr dispersoid phase was observed (Fig. 12). The tensile strength of the alloy at 300°C was superior to other commercial Al alloys. Although the increase in tensile strength at elevated temperatures was not very significant, the creep resistance increased due to the precipitation of fine, thermally stable $\epsilon\text{-AlSiZrTi}$ dispersoids within the intradendritic regions. The combined addition of Zr and Mn did not produce a pronounced effect on strength or creep strength (stress to produce 0.1% creep strain at 100 h) but delayed the tertiary creep stage in the T7 condition. Because of Mn addition and modification of iron-rich intermetallics, this alloy has better ductility over a broad temperature range (Table 4).

Table 5 Mechanical properties of the A356- and A319-based diesel engine alloys^[5]

Alloy	Room temperature			YS(MPa)	UTS(MPa)	E (%)	Creep $\sigma_{0.1\%}$ *(MPa)
	YS(MPa)	UTS(MPa)	E (%)				
A356	257	299	9.9	40	43	34.5	21.7
A356+0.5Cu	275	327	9.8	40	44	34.6	21.8

Note: *Stress at which 0.1% creep deformation occurs in 100h.

**Fig. 12** Al-Si-Zr-Ti precipitation (indicated by arrows) inside the dendrites^[5]

In 2006, Ozbakir and Pekguleryuz^[39] embarked on a similar alloy development route for Al Diesel engines. A356 was alloyed with (i) Cu; (ii) Zr, Cr, Mn, Ti; and (iii) Cu, Cr, Mn, Ti. It is known that Cr produces submicron precipitates in Al enhancing strength and aging response in wrought alloys.^[44,45] Cu addition together with Cr, Zr, Ti, and Mn was made to provide λ -phase strengthening in addition to β -phase strengthening in aging. The 0.15% Cr and 0.15% Mn addition in A356 caused the formation of blocky-type α -(Al-Cr-Mn-Fe-Si) phase instead of the needlelike β -AlFeSi phase. The addition of 0.15% Zr formed the eutectic platelike ϵ -(Al-Si-Zr) phase instead of the peritectic binary Al_3Zr in A356 alloys (Fig. 13a). Sometimes, Ti was also observed in this new ternary phase. Alloys solutionized at 500°C for 4h and at 540°C

for 10h precipitated out fine (<400 nm) intradendritic α -(Al-Cr-Mn-Fe-Si) and ϵ -(AlSi-Zr) precipitates (Fig. 13b). The eutectic α - and ϵ -phases remained in the interdendritic regions after solutionizing. All alloys were age hardened to T7 (200°C, 7h). The Al-7Si-0.5Cu-0.3Mg-0.15Cr-0.15Zr-0.16Mn-0.11Fe+0.12Ti alloy (MG2) showed higher peak strength (T6) and overaged strength (T7 @200°C, 7h) than the commercial A356 (R1) and the A356+0.5Cu (R2) as well as A356 with only the Cr, Mn, Ti (MG1) as shown in Fig. 14. The A356 and A356+0.5Cu did not exhibit much intradendritic precipitation. The total amount of the intradendritic precipitates of the MG2 alloy was higher than the MG1 alloy in the overaged condition due to the combined addition of Cr, Zr, Mn, and Cu (Fig. 15). The compositions of the creep-tested samples are shown in Table 6. The addition of 0.5% Cu improved the compressive creep resistance at the early stages of the creep testing at 300°C (Fig. 16). On the other hand, the peritectic addition without Cu (MG1) leads to only small but consistent decrease (approximately 8%–14%) in total creep deformation. The MG2 alloy shows superior creep resistance almost three times better than all of the alloys at all stages of the creep testing (up to 300h).

Mo-Modified Alloys

In a recent study by Farkoosh, Chen, and Pekguleryuz,^[47] molybdenum was identified in Diesel alloy strategy for its potential for dispersoid formation. Mo has low diffusivity in Al and solid and liquid solubility at the peritectic

**Fig. 13** SEM micrographs of as-solutionized MG2 showing (a) interdendritic eutectic phases and (b) fine α -(Al-Cr-Mn-Fe-Si) intradendritic precipitates

reaction temperature. Mo-containing alloy (MG3R3M: Al-7Si-0.6Cu-0.3Mg-0.3Mo) was investigated. It was seen that Mo formed nanoscale coherent dispersoids through a high-temperature solution treatment. (Fig. 17). The alloy was soaked at 500°C for 4h and held at 540°C for 16h to assess thermal stability. The dispersoids exhibit good thermal stability and provide strengthening to the alloy upon prolonged exposure (Fig. 18). It was seen that the Mo-containing dispersoids (indicated by arrows in

Fig. 19) remain unchanged during the prolonged aging, while both θ -Al₂Cu and Q-Al₅Cu₂Mg₈Si₆ precipitates become coarsened.

The Mo-containing alloy (Al-7Si-0.6Cu-0.3Mg-0.3Mo) exhibited significant improvement in mechanical properties at 300°C compared to the base alloy. A 90%–95% decrease in the minimum creep rate was observed at 300°C and 30 MPa, and the creep time-to-fracture increased by two orders of magnitude (Fig. 20). The very low creep rate

Fig. 15 Fine intradendritic precipitates in the overaged (a) R1, (b) R2, (c) MG1, and (d) MG2

Table 6 Chemical compositions of creep-tested samples (wt%)^[39]

Alloy	Si	Cu	Mg	Fe	Mn	Cr	Ti	Zr	V	Zn	Sr (ppm)
R1	6.74	<0.1	0.34	0.10	<0.01	<0.01	0.12	<0.01	<0.01	<0.01	160
R2	7.06	0.54	0.35	0.11	<0.01	<0.01	0.11	<0.01	<0.01	<0.01	190
MG1	6.60	<0.1	0.33	0.11	0.15	0.15	0.12	0.16	<0.01	<0.01	160

**Fig. 16** Compressive creep curves of the alloys at 300°C under 30 MPa^[39]**Fig. 17** (a)TEM micrograph showing the α -Al-(Fe, Mo)-Si dispersoids in the Al-7Si-0.6Cu-0.3Mg-0.3Mo alloy formed after 10h of solution treatment at 540°C. (b) EDS spectrum of the Al-(Fe, Mo)-Si dispersoids^[47]

of the Mo-containing alloy during a long thermal exposure period (100h soaking and 300h creep at 300°C) also indicates that the Mo-containing dispersoids are thermally stable at 300°C. The coarsening rate constant, K , of the precipitates can be estimated using^[48]

$$K \propto \frac{\gamma DC_m}{RT},$$

where γ = interfacial free energy, D = diffusivity of the rate-controlling solute atoms, C = solubility limit of the rate-controlling solute atoms, and RT has its usual meaning. K value for Mo-containing dispersoids (MG3R3M alloy) at 300°C is in the order of $\sim 10^{-33} \text{ mol}\cdot\text{s}^{-1}$, which is almost negligible compared to the K value for Cu-bearing precipitates at this temperature, $\sim 10^{-22} \text{ mol}\cdot\text{s}^{-1}$. Parameters used to estimate the K values are given in Table 7.

Fig. 20 Creep deformation at 300°C, 30MPa (a) tension, (b) compression. 1 h solution treatment at 540°C, 5 h aging at 200°C, and pre-soaking at test temperature for 100h

At 300°C, the tensile yield strength increased by 25% and elongation by 34% (Fig. 21). These effects were attributed to the formation of the dispersoids with approximate stoichiometric formula of $\text{Al}_{22}(\text{Fe}_{6-8}\text{Mo})\text{Si}_4$, as determined by quantitative EDS. Their crystal structure was

BCC with lattice parameter, $a_o = 12.54 \pm 0.03 \text{ \AA}$ and space group Im3. The orientation relationship most commonly observed between the Al matrix and dispersoids was $\langle 001 \rangle_d // \langle 001 \rangle_m$ and $\{350\}_d // \{002\}_m$. The precipitation of the dispersoids in large amounts and their coherency was

Fig. 21 SEM images after tensile creep testing at 300°C, 30 MPa. (a) The base alloy shows creep cavitation damage at 30 min, while (b) the Mo alloy has not reached the cavitation damage stage even after 10 h^[49]

accounted for by the structural correlation that was found between the BCC dispersoid phase and the FCC Al matrix.

Selected area electron diffraction analysis was performed,^[50] which showed that the dispersoids have a strong orientation relationship with the Al matrix (Fig. 22) given as $\langle 001 \rangle_d // \langle 001 \rangle_m$ and $\{350\}_d // \{002\}_m$. High-resolution TEM investigation and crystal structure simulations showed that there is a coherency of the atomic planes at the interface between the dispersoids and the Al matrix, which is related to the structural correlation between these two phases. The dispersoids with Mo have unique characteristics that make them effective strengtheners;

they are semicoherent with high coherency strain (~6%), which is unlike other Fe-containing dispersoids form in Al alloys alloyed with Cr and Mn are either incoherent or semicoherent low coherency strain (~1%).

Mo–Mn-Containing Alloys

Recent study by Farkoosh, Chen, and pekguleryuz^[51] has shown that molybdenum (Mo) in combination with Mn can form uniform dispersoids in large volume fraction in Al-Si-Mg-Cu casting alloy, which is a key achievement in designing dispersoid strengthened

Fig. 22 Common orientation relationship between the dispersoids and the matrix is $\langle 001 \rangle_d // \langle 001 \rangle_m$ and $\{350\}_d // \{002\}_m$, respectively

Fig. 23 BF-TEM images and the particle size distribution of the dispersoids after (a) 1 h and (b) 10 h of solution treatment at 540°C. Finer dispersoids of the micrograph (a) show coherency strain^[51]

Al alloys. The dispersoids possess a BCC crystal structure with a space group of Im3, and the lattice parameter of $a_0 = 12.56 \pm 0.04 \text{ \AA}$. This phase is structurally isomorphous with the $\alpha\text{-AlFeSi}$ intermetallic and has an approximate stoichiometric formula of $\text{Al}_{22}(\text{Fe}_{1.3}\text{Mn}_{4.6}\text{Mo})\text{Si}_4$. It has been reported that the $\alpha\text{-AlFeSi}$ transforms into a SC structure (Pm3 space group)^[52,53] at high Mn:Fe ratio but it was seen^[51] that Mo has a stabilizing effect on the BCC structure. While Mo stabilizes the BCC structure that is closely correlated with the FCC Al, Mn increases the volume fraction of the dispersoids without altering their structure. The opposite partitioning behavior of Mn and Mo ($k_{\text{Mo}} > 1$ vs. $k_{\text{Mn}} < 1$) during solidification leads to a uniform distribution of dispersoids with a negligible dispersoid-free zone. An alloy with Mo/Mn combined addition (MG3R3M15Mn: Al-7Si-0.5Cu-0.3Mg-0.1Fe-0.3Mo-0.15Mn) was studied^[51] in comparison to an alloy with only Mo addition

(MG3R3M: Al-7Si-0.5Cu-0.3Mg-0.1Fe-0.3Mo). The alloys were solutionized at 540°C to form the precipitates. 1 h and 10 h solutionizing was investigated (Fig. 23). The dispersoids formed in short solutionizing time showed coherency strains.

Creep testing of the alloys performed at 300°C and 26 MPa (creep conditions at Diesel engine heat-up) resulted in minimum creep rates ranging from 10^{-9} to 10^{-4} s^{-1} that demonstrate excellent creep resistance (Fig. 24a). The minimum creep rate decreased with Mn content at 300°C, 30 MPa (Fig. 24b). The creep time-to-fracture also increased from ~25 to ~180 h as Mn increased from 0.0% to 0.5%. Figure 25 shows the TEM images of the two alloys after 300 h creep testing. The dislocation arrangement in both alloys provides evidence for the dislocation pinning by the dispersoids. The alloy seems to be good candidate for further evaluation for use in elevated temperature engine applications.

SUMMARY AND FUTURE TRENDS

Studies on Diesel engine alloy development indicate that certain alloying addition is of potential use for improving the thermal fatigue resistance of Al-Si alloys.

1. Cu addition around 0.5% Cu improves the strength up to 200°C and is important for maintaining tensile strength during engine cooldown.
2. Increasing the Mg levels toward 0.5 wt% in Al-Si-Cu-Mg generates larger thermally persistent Q precipitates that improve elevated temperature strength. However, ductility decreases.
3. Al-Fe-Si intermetallics can be detrimental to ductility. It is seen that the 0.15% Cr and 0.15% Mn addition in A356 causes the formation of blocky-type α -(Al-Cr-Mn-Fe-Si) phase instead of the needlelike β -AlFeSi phase that improves ductility.
4. A large amount of thermally stable intradendritic dispersoids is extremely important for dislocation pinning that improves both elevated temperature strength and creep resistance. Here, a key design principle is to make a combined addition of slow-diffusing alloying elements with opposite solute segregation behavior ($k < 1$ vs. $k > 1$) to achieve a high density of precipitate with a uniform distribution. The role of the solute-solute interaction in forming dispersoids should also be taken into consideration. Dispersoid-matrix interface coherency can be possible with identical atomic configuration of the dispersoid and matrix phases. Crystal structure similarity can also facilitate nucleation of the dispersoids, increasing the number density.

5. The combined addition of Mo/Mn to Al-Si-Cu-Mg creates thermally stable and coherent dispersoids in high volume fraction. These alloys should be optimized and further evaluated on castability and other properties (e.g., fatigue) as well as via bench testing to further assess the elevated temperature performance in Diesel engine operation. The use of Mn with other transition metals is also of interest.
6. In-depth characterization of dispersoids and precipitates and understanding their role in dislocation creep are needed to further develop alloy design principles for Al Diesel engine alloys.

ACKNOWLEDGMENTS

The authors are thankful for the financial support of Natural Sciences and Engineering Research Council (NSERC) of Canada in enabling their own work on Diesel engine alloy development. A part of that work was carried out under an NSERC Strategic Project Grant with Rio Tinto Alcan (RTA) as the industrial partner. Prof. Pekguleryuz acknowledges the very valuable discussions with Fred Majors of RTA on the thermal fatigue mechanisms. Prof. Pekguleryuz is also grateful for the financial support of the NSERC Discovery program, the FRQNT (Fonds de recherche du Quebec-Nature et technologies) Team Grant and REGAL (Regroupement strategique sur l'aluminium) research grant. Dr A. Farkoosh gratefully acknowledges the McGill Engineering Doctoral Award (MEDA) for the partial support of his doctoral studies. E. Ozbakir is grateful for the Alcan Award in partial support of his graduate degree at McGill University.

Abstract

Diffusion bonding is a solid phase welding process in which bonding occurs through coalescence of the surfaces in contact. The principal operating parameters of diffusion bonding are the temperature, pressure and the bonding time. In addition to diffusion, other mechanisms such as microscopic creep or recrystallization also contribute to the formation and development of the bond. This article examines the influence of the surface oxide and welding atmosphere on mechanical characteristics of the bonded joint.

Keywords: Bonding temperature; Bonding time; Diffusion bonding; Surface oxides.

INTRODUCTION

Diffusion bonding is a solid phase welding process in which bonding occurs through coalescence of the surfaces in contact. The principal operating parameters of diffusion bonding are the temperature, the pressure and the bonding time. In addition to diffusion, other mechanisms such as microscopic creep or recrystallisation also contribute to the formation and development of the bond. Diffusion bonding can in some cases lead to the complete disappearance of the initial interface, and the joint thus formed has mechanical properties identical to those of the parent metal. One of the important features of diffusion bonding is that the deformations which occur during the process remain localised in the immediate vicinity of the interface, so that the overall deformation of the sample is very small.

Ideally, two perfectly clean (free of any contamination) and atomically flat surfaces should bond together spontaneously, even at ambient temperature, under the effect of the interatomic forces.

In practice, the solid phase bonding conditions are far from the ideal. Indeed, despite all the precautions taken, it is impossible to obtain a perfectly clean and smooth surface. Whatever its method of preparation, a surface is always rough on the microscopic scale and the actual contact is made on a very small part of the apparent surface. After polishing, asperities with a height of 10^4 Å are common.^[1-5] Moreover, in the air and at ambient temperature all metals apart from gold are covered with a natural film of oxide between 20 and 100 Å thick. To promote diffusion bonding, one can consider removing this film of oxide, in

particular by mechanical means. But for most materials the film of oxide quickly reforms, so that it is inevitably present at the interface. Since the height of the asperities and the thickness of the oxide film are much greater than the inter-atomic distance, the attraction forces are unable to act and consequently other mechanisms must help to form the bond.

The model generally accepted^[6-15] to describe the diffusion bonding mechanism contains two main stages. The first consists of the establishment and development of physical contact between the surfaces by plastic deformation and micro-creep of the asperities, while the second stage is characterised by atomic diffusion on each side of the interface and by the elimination of the residual pores. However, in reality there is no clear demarcation between these two stages. The state of the surfaces in contact determines the possibility of migration of the atoms across the initial interface to a great extent, and consequently plays a very important role.^[16] The films of oxide and of contamination, which form a diffusion barrier, must be removed before or during the bonding operation. Because of the relatively high temperatures involved in diffusion bonding, this removal can take place by dissolution into the parent metal. Only a few materials have surface oxides stable and tough enough to be a problem at a bonding temperature of $0.7 T_f$ ^[17] where T_f is the melting point of the parent metal. For these, a notable improvement can only be obtained for bonding temperatures very close to the melting point. Aluminium and its alloys fall into this latter category of materials.^[6,18-25]

Despite these difficulties, diffusion bonding appears to be an assembly process well suited for joining aluminium

alloys of the 2000 series. In fact, this type of bonding, avoiding the melting of the material, makes it possible to overcome the hot cracking problems of these alloys. In an earlier study^[26,27] we showed that it is thus possible to obtain welded joints in A2017 aluminium alloy having a tensile strength similar to that of the parent metal.

The present study refers to the same alloy and complements our earlier results, particularly for long welding times. Moreover, special attention is given to studying the influence of the surface oxide and of the welding atmosphere on the mechanical characteristics of the bonded joint.

EXPERIMENTAL METHODS AND MATERIAL

Parent Metal

The parent metal used for this study was commercial A2017 aluminium alloy, delivered in metallurgical state T4 (quenched-aged) and with the chemical composition shown in the Table. The welded assembly consisted of two 10 mm diameter cylindrical samples, each 15 mm long.

Operating Conditions

Chemical composition of the parent metal, wt %

	Si	Fe	Cu	Mn	Mg	Cr	Zn	Ti+Zr	Al
Min	0.20		3.5	0.4	0.4				
Max	0.8	0.7	4.5	1.0	1.0	0.1	0.25	0.25	bal

After machining, the contact surfaces were polished mechanically. In the earlier study,^[26,27] three types of surface preparation (polishing with emery paper of grade 180 or 1200, polishing with 1 μm grinding paste) has been used. In this study, we restricted ourselves to using emery paper of grade 1200. In this case the surfaces showed asperities with a maximum height, H_{max} , of 4.5 μm . After polishing, the samples were degreased and cleaned with acetone in an ultrasound tank, then dried. Immediately after these cleaning operations, the samples were positioned in the welding chamber in such a way that the polishing marks of the two surfaces brought into contact were orientated perpendicularly.

The diffusion bonding was carried out under a secondary vacuum of about 10^{-3} Pa, using the experimental rig described previously.^[26,27] Except where otherwise indicated, the bonding pressure and time used in this study were respectively 2 MPa and 30 min. This choice was made in view of the earlier results,^[26,27] and represented a compromise between the search for a good tensile strength of the joint and for low bonding deformation.

Fig. 1 Schematic representation of the bonding cycle (T_s and t_s are respectively the bonding temperature and time)

The bonding pressure was kept constant throughout the process and during the in-situ cooling of the sample. When the sample temperature reached about 225°C during the cooling, the pressure was removed and the sample was taken out of the chamber. The cooling then continued in the laboratory atmosphere. A typical bonding cycle is shown schematically in Fig. 1.

After bonding, the joint was mechanically investigated by a static tensile test ($\dot{\epsilon} = 10^{-3}\text{s}^{-1}$) at ambient temperature. This investigation was completed by microscopic observations of the interface.

EARLIER RESULTS ON THE DIFFUSION BONDING OF A2017 ALUMINIUM ALLOY

Our earlier study,^[26,27] enabled us to show up the effects of the principal operating parameters (temperature, pressure, bonding time and surface preparation) on the mechanical characteristics of the bonded joints. The work was done within a temperature range 450–600°C and with bonding pressures of 2–10 MPa and hold times of 30 and 60 min. The principal results obtained may be summarised as follows:

1. Temperatures of more than 550°C are necessary in order to make sound joints with a recrystallised structure through the initial interface. At these temperatures, the presence of a small quantity of liquid phase at the interface favours the bonding process.
2. Beyond 550°C, the tensile strength of the joint remains constant at around 300 MPa, whatever the bonding pressure and time, and also whatever the surface roughness. It is however advisable to choose times and pressures which are as low as possible, to minimise the bonding deformations.
3. At low bonding temperatures, i.e. in the absence of any liquid phase, the mechanical strength of the joint is generally greater as the bonding pressure or time increase.

4. A certain surface roughness, by encouraging the breakup of the oxide film and consequently the establishment of metal contact at the interface, is beneficial to the bonding, but only when the latter is made between 450 and 525°C.

NEW EXPERIMENTAL RESULTS AND DISCUSSION

Influence of the Surface Oxide

General

Although some authors^[1,28,29] mention the possibility of bonding between oxidised surfaces, the presence of a film of oxide is generally considered to be harmful. This film can firstly act as a diffusion barrier by preventing the establishment of metallic contact,^[5,30–33] and secondly block the growth of the grains through the initial interface.^[1,23] To minimise growth of the oxide film during heating, diffusion bonding is normally carried out under a secondary vacuum or in an inert (argon) atmosphere.^[10,31–34] However, Tylecote^[1] and Karlinski^[29] note that at ambient temperature an ordinary vacuum of 10^{-5} torr (about 1.3×10^{-3} Pa) is not enough to cause dissociation of the oxides from most metals and to prevent certain of them oxidising. Therefore, while the presence of a protective atmosphere reduces the problem of oxide formation, it does not prevent it completely. The presence of some residual oxide on the surfaces to be joined is therefore inevitable.

This controlled bonding atmosphere is an operational constraint which it would be interesting to be able to overcome. Various authors^[35–37] have proposed an ‘auto-vacuum’ bonding and cleaning method which allows the bonding to be done in the ambient air with no protective atmosphere. To do this, the periphery of the joint is sealed, generally by fusion welding, and the heating of the work piece causes a dissolution of the oxides into the parent metal and a desorption of the gases trapped between the surfaces in contact, thus creating a vacuum at the interface. The quality of the joints made with this technique, particularly with ASI 1020 steel,^[37] can be fully comparable with that of joints made under vacuum. However, while this method offers undeniable advantages for parts of large dimensions, it also has the major disadvantage of requiring a possible post-weld machining operation to remove the sealing bead.

The time elapsing between the end of the surface preparation phase and the beginning of the bonding operation, and the storage conditions during this period, are parameters which to a large extent determine the thickness of the residual oxide film at the interface. Similarly, the quality of the vacuum in the welding chamber also has an important effect on the growth of this interfacial oxide film during the bonding process. These different parameters must therefore be controlled.

Influence of the Hold Time in Air before Bonding

In the earlier study,^[26,27] the samples were placed under vacuum in the welding chamber immediately after the preparation of the surfaces. The exposure to the ambient atmosphere between these two operations lasted for less than one minute. Working this quickly prevents the oxide film from reforming too fast, but is nevertheless an operational constraint difficult to incorporate in an industrial process.

To get a better understanding of the importance of this parameter, we studied the effect of the air oxidation time of the surfaces before welding on the mechanical characteristics of the bond (Fig. 2). This oxidation, occurring immediately after the surface preparation, took place either in the ambient atmosphere of the laboratory or in an oven at 30°C.

The scatter of the results obtained on the samples oxidised in the ambient atmosphere of the laboratory was very considerable. These large fluctuations were probably the result of poor control of the oxidising conditions. In particular, the moisture in the air can differ greatly from one test to another, and has a considerable effect on the quality of the welded joint.

By contrast, holding at 30°C in an oven provides oxidation kinetics which are constant in time. In this case, the changes in the tensile strength of the joint according to the oxidation time showed two different aspects. For oxidation times of less than about 30 to 40 min, the tensile strength of the joint fell relatively quickly with the oxidation time. It then remained more or less constant at around 200 MPa for oxidation times between 40 min and 3 hours. This evolution of the mechanical bonding characteristics appears directly linked to the changing thickness of the Film of oxide at the interface. In fact, the work by Tylecote et al.^[38] showed that the thickness of the film of aluminium oxide increased rapidly during the initial stage of the oxidation process, before becoming more or less constant. In view of these results, it appears desirable to carry out the bonding as quickly as possible after the surface preparation.

Fig. 2 Effect of the pre-bonding oxidation time on the tensile strength of the bonded joints (bonding parameters: 575°C, 2MPa, 30min)

Figure 3 presents micrographs of the interface of joints bonded at 575°C immediately after surface preparation (Fig. 3a) or after 1 hour exposure at 30°C in an oven (Fig. 3b). Recrystallised structures are observed in both cases; but the interface geometry of these joints is very different. The sample bonded immediately after surface preparation (Fig. 3a) shows grain growth through the initial interface causing a movement of the latter. By contrast, the interface of the sample bonded after 1 hour oxidation in the oven (Fig. 3b) remains rectilinear. This different appearance of the joint line could account for the 100MPa difference between the tensile strengths of the two joints (Fig. 2).

Influence of the Bonding Atmosphere

To show the importance of the bonding atmosphere, tests were performed in both a primary vacuum (above 1 Pa) and a secondary vacuum (above 10^{-3} Pa), the other operating parameters remaining constant. The maximum tensile strengths of these two types of joint are shown in relation to the bonding temperature in Fig. 4.

The results obtained clearly indicate that the mechanical properties of the joints bonded in a primary vacuum are greatly inferior to those of the joints made in a secondary vacuum. The difference in quality between the two types of joint increases with the bonding temperature.

Further tests were performed directly at atmospheric pressure. In this case the hot oxidation was very considerable, and it was impossible to obtain any bonding despite the high temperatures and pressures (respectively 575°C and 5 MPa).

The metallographic structure of the joints bonded in a primary vacuum (Fig. 5) at 575°C for 30 min was comparable with that of joints bonded at the same temperature in a secondary vacuum after one hour oxidation in an oven (Fig. 3b). In both cases, the interface remained rectilinear and the mechanical properties of the joints were very similar.

Influence of Bonding Time and Temperature

The influence of bonding time is not independent of bonding pressure and temperature.^[13,39] According to the value of these latter two parameters, the time required to obtain

Fig. 4 Effect of the bonding atmosphere on the tensile strength of the bonded joints

Fig. 5 Microstructure of a joint bonded in primary vacuum (bonding parameters: 575°C, 2 MPa, 30 min)

a diffusion bond can range from a few minutes to several hours.^[10–30]

At bonding temperatures slightly below the temperature at which the liquid phase appears (above 525°C), our earlier tests^[26,27] showed that an increase in the bonding time from 30 to 60 min considerably improved the quality of the bonded joint. This preliminary study was extended in the present work to times of 14 hours, the bonding pressure always remaining at 2 MPa. The results obtained (Fig. 6) show that for bonding temperatures higher than 550°C, the tensile strength of the bonded joint falls as the bonding time rises. This harmful effect of the bonding time may be

Fig. 3 Microstructure of the bonded joint (bonding parameters: 575°C, 2 MPa, 30 min: (a) Immediately after polishing; (b) After 1 hour at 30°C in oven

Fig. 6 Effect, for a given hold time, of the bonding temperature on the tensile strength of the bonded joints

related to the presence, at these temperatures, of a small quantity of liquid phase at the interface.

At temperatures of 525°C or less, bonding actually occurs in the solid phase and an increase in the hold time generally has a beneficial effect on the quality of the bonded joint. However, we find that between about 500 and 525°C, the joints with a bonding time of 14 hours show a lower mechanical strength than the joints with a one hour bonding time. This may appear paradoxical. It can also be seen that the joints bonded in 1 hour at 500°C and those bonded in 14 hours at 475°C show identical mechanical characteristics.

Figure 7, obtained for different bonding temperatures, illustrates the effect of the hold time on the tensile strength of the bonded joints. This figure takes account of a number of results obtained for 6 hour bonding times.

According to the bonding temperature, the tensile strength of the bonded joint shows three different kinds of variation with time. At low temperatures (450 and 475°C), the mechanical strength of the joint increases with bonding time. We may expect that for even longer times, these

Fig. 7 Effect, for a given bonding temperature, of the hold time on the tensile strength of the bonded joints

curves would stabilise at a certain level. Therefore, at low temperatures, time has a beneficial effect on the quality of the bond since it increases diffusion. In contrast, for high bonding temperatures (550 and 575°C), a reduction in the tensile strength of the joints occurs as the bonding time increases. However, at the mid-range bonding temperatures (500 and 525°C), the tensile strength of the joint increases very quickly during the first hour's bonding. For longer hold times, it decreases and tends to stabilise at values of around 150 MPa. These temperatures correspond approximately to the threshold at which the liquid phase appears, although the latter is in very minimal quantities and only affects the quality of the bonded joint after a certain hold time.

The bonding deformations, defined as the growth in cross section of the sample at the interface during bonding, are practically identical for the three bonding times considered. These deformations are less than 0.4% for bonding temperatures within the 450–550°C range, and reach values of around 1% at a bonding temperature of 575°C. The elongation at fracture of the bonded samples varies similarly to the tensile strength.

Figure 8 shows a micrograph of the interface of a joint bonded at 575°C after a hold time of 14 hours. Comparing this micrograph with that of a sample bonded for only 30 min (Fig. 3a), it is difficult to explain the difference in mechanical strength between these two joints.

CONCLUSIONS

This study, carried out on A2017 aluminium alloy, allowed the harmful effect of a period of exposure to air between the surface preparation and the bonding operation proper to be revealed. An excessive exposure period encourages reformation of a film of oxide at the interface which interferes with the subsequent bonding process and lowers the mechanical properties of the bonded joints. It is therefore desirable to keep this period as short as possible, and if this cannot be done it is vital to exercise proper control over the storage conditions and in particular the moisture content of the air.

Fig. 8 Microstructure of a joint bonded at 575°C for 14 hours (bonding pressure: 2 MPa)

Similarly, the vacuum in the welding chamber is an important factor. A secondary vacuum of around 10^{-3} Pa appears necessary to obtain sound and strong joints.

Moreover, this study showed that the effect of the hold time on the tensile strength of the joint is closely related to the bonding temperature. This behaviour appears to be directly linked to the presence or otherwise of a proportion of liquid phase at the interface. When the latter is absent (at lower temperatures), a rise in the hold time tends to increase the mechanical strength of the bonded joint. On the other hand, its presence allows a very good bond to be obtained, on condition that the bonding time is kept relatively short. It would therefore appear that the optimum bonding conditions are a temperature of 575°C, a pressure of 2 MPa and a hold time of 30 min. Under these conditions, the tensile strength of the bonded joint is around 320 MPa, little different from that of the parent metal.

Dispersoid Precipitation in Aluminum Alloys

Joseph D. Robson

School of Materials, MSS Tower, University of Manchester, Manchester, M13 9PL, United Kingdom

Abstract

Dispersoid particles are critical to the control of recrystallization and grain growth behavior during thermomechanical processing of wrought aluminum alloys. The precipitation of dispersoids has some unique characteristics that must be considered to understand the microstructure and properties obtained in the final product. Dispersoids precipitate from a segregated cast structure and therefore are inhomogeneously distributed within a grain. They often precipitate from other phases that form during heating and then redissolve. Finally, their precipitation is often in competition with other microstructural processes, for example, a change in composition of the constituent phases. Understanding these factors is critical to control dispersoid precipitation. Furthermore, the increasing demand to replace primary aluminum with recycled material requires careful control of the dispersoid-forming elements, which tend to accumulate during recycling. Small changes in the amounts of these additions can have a large effect on recrystallization behavior and hence texture and properties.

Keywords: Dispersoids; Homogenization; Precipitation; Recrystallization.

INTRODUCTION

Dispersoid particles are commonly used in wrought aluminum alloys to control the grain structure during thermomechanical processing by controlling recrystallization and grain growth.^[1,2] To be useful in this role, dispersoids must be precipitated from solid solution in a controlled way to obtain a distribution of small ($<0.3\ \mu\text{m}$), finely distributed particles that are stable during high temperature annealing or solution treatment. This necessarily requires dispersoid-forming elements to have a low solubility and low diffusion coefficient in the matrix. These fundamental requirements are key to the precipitation behavior of dispersoid particles.

Typical dispersoid-forming elements (e.g., Cr, Mn, Zr) have maximum solid solubilities in aluminum of approximately 0.35, 0.6, and 0.08 at%, respectively.^[3,4] It is therefore clear that the amount of these elements that can be retained in solid solution in aluminum for any conventional process route is necessarily very limited, and the maximum volume fraction of dispersoids that can be precipitated is small ($<1\%$). It is for this reason that dispersoid particles do not usually make a significant direct contribution to alloy strength (by blocking dislocation glide). However, their effect on grain structure, stored dislocations, and slip localization can be profound.^[5–7] They can also have a strong interaction with the formation of the age hardening precipitates that do provide strengthening in heat treatable alloys.^[8] In this way, dispersoids influence many of the alloy properties, for example, strength, fracture toughness, fatigue resistance, and corrosion resistance. Understanding

these effects requires an understanding of the mechanisms of dispersoid precipitation.

DISPERSOID PHASES

All of the dispersoid phases in aluminum alloys are intermetallic compounds of aluminum. A large number of phases are possible depending on the specific dispersoid-forming element added and the composition of other elements in the alloy. Even within the same alloy system (e.g., 6xxx Al-Mg-Si) and with the same dispersoid-forming additions (e.g., Mn, Cr), there is a possibility to form different dispersoid phases depending on the ratio of the alloying elements.^[9]

- An important distinction to make is between dispersoid phases that also contain some of the major alloying elements and dispersoid phases that precipitate without absorbing other alloying elements. An example in the former category is $\text{Al}_{12}\text{Mg}_2\text{Cr}$ (formed when chromium is added, but absorbing some magnesium), and the main example in the latter category is Al_3Zr , which does not require other alloying elements to form.

The major dispersoid phases exploited in aluminum alloys are summarized in Table 1, with examples given of typical alloys in which they form.^[2,10–12] It should be noted that although the compositions of such phases are often reported as conforming to an exact stoichiometry, detailed measurements suggest this is rarely the case, and usually

Table 1 Common dispersoid phases exploited in aluminum alloys and example alloys in which they occur

Phase	Dispersoid addition	Other elements	Example alloys
$\text{Al}_6(\text{Mn, Fe})$	Mn	Fe	5182
$\alpha\text{-Al}_x(\text{MnFeCr})_y, \text{Si}$	Mn (Cr)	Fe, Si	6006, 3003
$\text{E-Al}_{12}\text{Mg}_2\text{Cr}$	Cr	Mg	7075
$\text{T-Al}_{20}\text{Mn}_3\text{Cu}_2$	Mn	Cu	2024
$\beta'\text{-Al}_3\text{Zr}$	Zr	—	7050, 2195

there is a composition range that depends on the alloy composition and precipitation conditions.

ROLE OF AS-CAST STRUCTURE

Dispersoid-forming elements are added in sufficient quantity to be in a supersaturated state following casting of the alloy. This means that, given the opportunity, they will seek to precipitate out to reduce the supersaturation and lower the free energy of the matrix. Since the dispersoid-forming elements are chosen to be slow diffusers in the matrix, sufficient thermal energy must be supplied to enable the diffusion required for nucleation and growth, and this requires heating to temperatures above those used for precipitation in age hardening.^[2]

The casting processes used to produce aluminum alloy ingots for wrought processing (e.g., direct chill (DC) casting) lead to highly nonequilibrium solidification conditions. As a result, the as-cast ingot is characterized by nonuniform distribution of the alloying elements on both the scale of individual dendrites (microsegregation) and the entire casting (macrosegregation).^[1] The first heat treatment to be carried out after casting is homogenization, which may be combined with the preheat to the hot working process. The primary purpose of homogenization is to reduce the effects of microsegregation and dissolve nonequilibrium primary phases formed during casting. To achieve these goals in the minimum time, homogenization is usually carried out at the maximum possible temperature whilst avoiding incipient melting.^[1] This temperature is high enough to accelerate the diffusion of the sluggish dispersoid-forming elements sufficiently so they precipitate out, forming the dispersoid particles. However, it is important to note that dispersoid precipitation is often considered secondary to the primary purposes of homogenization.^[2] As such, the homogenization treatment time and temperature are rarely optimized to provide the best precipitation treatment for the dispersoids, but rather have to be chosen to satisfy the primary homogenization goals.

The observation that dispersoid precipitation occurs from an as-cast structure in which the alloying elements are nonuniformly distributed and the constraints placed on the precipitation conditions used for dispersoid formation have important consequences in determining dispersoid

size, spacing, and distribution, and hence their effectiveness in subsequent control of grain structure. This also adds considerably to the complexity of understanding and predicting dispersoid precipitation, since the spatial variation in composition means that in different parts of a grain, dispersoids will be precipitating in a different local environment.

The importance of the as-cast structure to the precipitation of dispersoids and their effectiveness in preventing recrystallization later during processing (solution treatment in this case) can be clearly seen for the example of AA7050 plate, in which the dispersoid-forming element is zirconium (Fig. 1).^[13,14] During solidification, (casting) zirconium is rejected from the liquid into the new solid. Therefore, the first solid to form, which is toward the dendrite center, has a higher zirconium concentration than the final solid to form. This can clearly be seen in a composition line-scan across a grain in the as-cast structure (Fig. 1a,b). During homogenization, the dispersoids (which in this case are Al_3Zr intermetallic particles) precipitate from the segregated structure, with insufficient time for significant redistribution of zirconium prior to their formation. This means that the pattern of dispersoid precipitation follows the original pattern of zirconium segregation. No dispersoids at all precipitate toward the edge of the dendrites because here the zirconium concentration in the casting is below the solubility limit at the homogenization temperature and therefore there is no supersaturation.

Toward the center of the dendrites, the zirconium supersaturation is greatest, and the volume fraction of dispersoids that forms is highest. Note that the size and number density of the dispersoids does not vary in a simple way with position (i.e., local composition) because of the competition between nucleation and growth in removing supersaturated zirconium from the matrix. This can be predicted by a model and is discussed in detail elsewhere.^[13] After rolling and solution treatment, regions where the dispersoid volume fraction (strictly, pinning pressure) falls below a critical level undergo undesirable recrystallization (Fig. 1).^[15] Only in regions where there is sufficient dispersoid precipitation to pin grain boundary migration is recrystallization prevented. The fraction and distribution of recrystallized grains in the final product thus has a direct link to the nonuniform distribution of zirconium in the original as-cast structure.^[6,15]

Fig. 1 The effect of microsegregation in the cast structure and the nonuniform distribution of Al_3Zr dispersoids in AA7050 and its influence on final recrystallization behavior. (a) As cast structure showing line-scan across a grain, (b) variation in zirconium along line-scan. Zirconium segregates to dendrite centers. (c) Dispersoid particles after homogenization; dispersoid-free regions occur in the low-zirconium area at the dendrite edges. (d) A partially recrystallized structure is observed after hot rolling and solution treatment; recrystallized grains (white regions) occur in regions where the dispersoids are depleted

The extent and sense in which a dispersoid-forming element is segregated in the cast structure depend on how the element is partitioned during the solidification process and can usually be predicted reasonably well by the Scheil Gulliver equations.^[6,13] In the case of Al_3Zr dispersoids, this is sufficient to estimate the variation of dispersoid volume fraction across a dendrite.^[6,13,16]

For other dispersoid-forming elements (e.g., Cr, Mn) the situation can be even more complex. This is because in these cases, there are other particles present or possible after casting that can compete with the dispersoids for the supersaturated solute Cr and Mn.^[17,18] In addition to being dispersoid formers, these elements are also incorporated into the primary constituent particles during casting.^[19] Upon homogenization, these insoluble constituents can undergo composition change or transformation, and this can draw in some of the dispersoid-forming solute.^[17,19] The competition between constituents and dispersoids for solute also influences the dispersoid stability after precipitation, discussed in detail later.

A final additional complication occurs because dispersoid precipitation is influenced not only by the distribution of the dispersoid-forming elements, but also by the distribution of other alloying elements in the matrix. This effect is particularly strong where the dispersoids form heterogeneously during heating on a phase formed from other alloying elements in the system.^[9] In such cases, the distribution of the other elements is also important

since this will determine the nature and distribution of the nucleating particles. Furthermore, diffusion during homogenization will lead to a continuous redistribution of these elements from solute-rich to solute-poor regions. These complex interactions can be manipulated by controlling heating rate, discussed in detail later. Even where there is only limited interaction between the dispersoid-forming element and other phases (e.g., when Zr is used as a dispersoid former), the distribution of the other alloying elements is significant because it influences the solubility of the dispersoid-forming element.^[20]

It is therefore clear that a good understanding of the cast structure (and in particular the microsegregation of the alloying elements) is needed to understand the precipitation of dispersoids.

PRECIPITATION MECHANISM

Unlike the age hardening phases in aluminum, most of the dispersoid phases (Table 1) do not have metastable variants that can nucleate readily. Instead, the large energy barrier to their formation necessitates that the dispersoid phases nucleate heterogeneously. The mechanism by which this occurs leads to considerable complexity in their precipitation behavior. The notable exception to this is the β' - Al_3Zr dispersoid phase, which is metastable and has an ordered face-centered cubic crystal structure (L1_2) that can form

a low-energy coherent interface with the matrix.^[21] However, the misfit strain associated with the formation of a coherent Al_3Zr nucleus is significant, and even in this case heterogeneous nucleation is often favored.^[21]

In general, there are two types of nucleation sites that are effective in promoting dispersoid formation. Dislocations provide favorable sites that reduce the energy barrier to nucleation and provide fast diffusion pathways for solute.^[22] The dislocation density in the as-cast state is low, so such sites are most effective when the dispersoids are precipitated from material in the deformed state. In age hardenable alloys, the most effective nuclei are usually provided by precipitates formed from the major alloying elements during heating up to the homogenization temperature.^[1,9]

The sequence of precipitation events can be very complex and is not yet fully understood in all cases. An example for a 6xxx series alloy is shown in Fig. 2.^[9] During the ramp up to homogenization (between approximately 100°C and 350°C), β' - Mg_2Si precipitates and coarsens. This phase provides a nucleus for a transition phase (called u-phase) to form. Further heating then leads to dissolution of the β' - Mg_2Si and nucleation of the $\alpha\text{-Al}(\text{MnFeCr})\text{Si}$ dispersoid phase on the u-phase. It may be appreciated that this sequence of events is very sensitive to the heating rate employed and also depends on the exact alloy chemistry (especially if both Mn and Cr are used as dispersoid formers).^[9,23] The heterogeneous nucleation of the dispersoid phase on a transitory precipitate phase during heat up is not confined to 6xxx alloys, but is a common observation. For example, Mg_2Si can also provide a nucleation site for $\alpha\text{-Al}(\text{MnFeCr})\text{Si}$ dispersoids in non-heat treatable 3xxx and 5xxx alloys.

In Al-Zn-Mg (7xxx) alloys, Al_6Mn dispersoids have been shown to nucleate on the interface of $\eta\text{-MgZn}_2$ particles during heating up to homogenization,^[1] and $\eta\text{-MgZn}_2$ interfaces can also provide potent nucleation sites for formation of $\beta'\text{-Al}_3\text{Zr}$.^[13]

EFFECT OF HEATING RATE AND HOMOGENIZATION CONDITIONS

As discussed in the previous section, transitory phases formed during heat up are often critical to accelerate the nucleation of the dispersoid phase. Since for maximum pinning pressure (resistance to recrystallization) the aim is to obtain a fine distribution of submicron particles, it is important to control heating rate to optimize dispersoid nucleation. In addition, to avoid large dispersoid-free regions, it is necessary to promote nucleation in regions where there may be insufficient supersaturation at the homogenization temperature. This can also be achieved by control of the heating ramp, or by incorporation of holds during heating at a temperature below the homogenization temperature.

In general, a slow heating rate to homogenization (e.g., $<75^\circ\text{C h}^{-1}$) is needed to allow sufficient time for the transitory phases to form and grow to a sufficient size to be potent as nucleation sites for the dispersoid phase.^[1] There is often a complex balance to be satisfied however, since in many cases the dispersoid phases are in competition for solute with transforming constituent phases located at the grain boundaries. For example, in 3xxx alloys, the diffusion of Mn from the matrix to the grain boundary (constituent) $\alpha\text{-Al}(\text{MnFe})\text{Si}$ leads to a depletion of Mn in the region next to the grain boundary and local dissolution of the $\alpha\text{-Al}(\text{MnFe})\text{Si}$ dispersoids.^[17,18]

As previously mentioned, the conditions (temperature, time) used for homogenization may well not be the optimum conditions for forming the best dispersoid distribution. In such cases, it can be useful to introduce a hold during the ramp to homogenization that coincides with the peak nucleation temperature for the dispersoid phase. Such an approach can lead to a refinement of the dispersoids (by allowing more particles to nucleate) and can help to promote nucleation in regions of low supersaturation. The result is that a more effective dispersoid distribution can be obtained to inhibit recrystallization. An example of this approach applied to the $\beta'\text{-Al}_3\text{Zr}$ dispersoids in AA7050 is shown in Fig. 3.^[14]

DISPERSOID STABILITY AND COARSENING

For the dispersoids to remain effective in pinning migrating grain boundaries, they must remain stable and small during downstream processing. To achieve this, both the solubility and the coarsening rate of the dispersoid particles need to be low. Low solubility is obtained by choosing an appropriate dispersoid-forming element. Coarsening rate is determined by interfacial energy and diffusion coefficient of the rate controlling species. For maximum resistance to coarsening, a dispersoid phase with a low interfacial energy formed from a slow diffusing species is required. All the commercially used

dispersoid-forming elements (Cr, Mn, Zr) have very slow diffusion rates in aluminum compared with that of the major age hardening additions. This leads to coarsening rates that are typically 5–8 orders of magnitude less than those of the strengthening phases in such alloys.^[24] It is this characteristic that enables the dispersoids to be retained as submicron particles, even after prolonged heating at temperatures close to the alloy melting point. The β' - Al_3Zr has the advantage of forming a low-energy coherent interface with the matrix, which further reduces coarsening rates.^[25]

As discussed previously, in nonage hardenable alloys, the elements used to form the dispersoid phase (e.g., Mn) are often the same as those bound up in the constituent phases, and there is an interaction between these particle populations. During prolonged thermal exposure, long-range diffusion of solute toward the constituent phases can lead to dissolution of dispersoids and a reduction in their volume fraction.^[17,18] An understanding of these interactions is important to understand the pinning effectiveness of the dispersoids and their influence on the recrystallization behavior. Since the dispersoids have a powerful effect on grain boundary migration, an understanding of their precipitation is important in attempting to predict recrystallization and grain growth-related phenomena. A number of predictive models have now been developed that attempt to simulate dispersoid precipitation and its effect on recrystallization, accounting for the previously mentioned interactions.^[13,17]

Fig. 3 The effect of introducing a hold during the heat up to homogenization for AA7050 (Al_3Zr dispersoids). (a) Without hold, fewer dispersoids form and the distribution is heterogeneous, leading to (b) a larger recrystallized fraction in the final plate. (c) With a hold, dispersoid nucleation is promoted, and a finer and more homogeneous distribution leads to (d) a reduced recrystallized fraction^[14]

DISPERSOID PRECIPITATION IN COMMERCIAL ALUMINUM ALLOYS

Non-heat Treatable Alloys

Al-Mn-based (3xxx series) alloys form dispersoids during homogenization or preheat treatments as a result of the presence of Mn, Fe, and Si. The dispersoid phase formed in commonly used 3xxx alloys (e.g., AA3003, AA3004) is $\alpha\text{-Al}(\text{MnFe})\text{Si}$, which will precipitate during the initial heat treatment but will continue to evolve during subsequent hot processing operations (e.g., rolling, extrusion). For 3xxx with lower Si contents, $\text{Al}_6(\text{Mn, Fe})$ dispersoids may be the dominant dispersoid phase instead.^[11]

In 3xxx alloys, the dispersoids not only have a strong influence on the evolution of the grain structure, but they also provide a significant direct strengthening effect and will influence the work hardening behavior of the material.^[26] There is also feedback in the opposite direction in that the dislocations introduced during deformation can provide potent sites for nucleation of dispersoids if there remains sufficient supersaturation of the dispersoid-forming elements during hot deformation or post-deformation annealing.^[22] Note that in 3xxx alloys, it is often required to obtain a recrystallized structure after final processing (e.g., to control the texture in can body stock). In such alloys, the role of dispersoids is not to prevent recrystallization, but to control it.

In commonly used 5xxx series, alloys such as AA5182, the free silicon content is usually too low to form the $\alpha\text{-Al}(\text{MnFe})\text{Si}$ phase, and instead the dominant dispersoid phase is $\text{Al}_6(\text{Mn, Fe})$.^[11,27,28] However, the dispersoid phase is sensitive to the exact alloy chemistry and heat treatment, and $\alpha\text{-Al}(\text{MnFe})\text{Si}$ dispersoids have been observed in commercial 5xxx alloys.^[26,29]

The $\text{Al}_6(\text{Mn, Fe})$ dispersoid particles form with a range of morphologies including rhombohedral, lath, and plate.^[11,27,28] The dispersoid morphology is sensitive to the heat treatment used to form them (e.g., temperature), and this in turn has a strong influence on their pinning effectiveness and thus influence on recrystallization behavior.^[28] In 5xxx alloys that contain Cr, the $\text{E-Al}_{12}\text{Mg}_2\text{Cr}$ dispersoid phase can form in addition to $\text{Al}_6(\text{Mn, Fe})$.^[2]

Note that the requirement for recycling places limitations on the dispersoid-forming elements used in 3xxx and 5xxx alloys and care must be taken to control the level of dispersoid-forming elements in recycled material to avoid unexpected changes to the precipitation behavior and hence final microstructure and properties.^[30]

In both 3xxx and 5xxx alloys, the dispersoid phase competes with constituent particles for solute. As discussed previously, this can lead to dissolution of dispersoids in the regions adjacent to large constituents on prolonged heating, leading to dispersoid-free zones adjacent to coarse constituent particles (which may themselves be preferential sites for recrystallized grains formed by particle stimulated nucleation).

Al-Mg-Si (6xxx) Alloys

The precipitation of α -Al(MnFeCr)Si dispersoids in 6xxx series alloys has already been discussed and has been shown to depend on the formation of a sequence of precursor phases on which the dispersoids nucleate.^[9,23] One consequence of this precipitation mechanism is that the distribution of dispersoids reflects the distribution and morphology of the transition phases. This, in turn, will influence the effectiveness of the dispersoids in pinning migrating grain boundaries. The use of other dispersoid-forming elements (e.g., Zr) in 6xxx alloys has also been explored. This has been shown to be effective in inhibiting recrystallization, although the metastable $L1_2$ dispersoids tend to transform to the equilibrium structure at the higher homogenization temperatures used in 6xxx alloys (compared to 7xxx alloys), which involves incorporation of Si into the dispersoids.^[31,32]

It should be noted that as with 3xxx and 5xxx alloys, the increasing trend to use recycled material has an important impact on dispersoid precipitation. The dispersoid-forming elements tend to accumulate during recycling and care must be taken to ensure that they remain within acceptable limits to avoid a significant change in dispersoid precipitation behavior (and even a change in dispersoid phase). Such a change can have a large impact on the recrystallization behavior and hence properties of the final product.

Al-Cu-Mg (2xxx) and Al-Zn-Mg-(Cu) (7xxx) Alloys

Traditionally, Mn and Cr were used as the dispersoid-forming additives in 2xxx and 7xxx alloys. For example, in AA2024, manganese additions are used to form $T\text{-Al}_{20}\text{Mn}_3\text{Cu}_2$ dispersoids and in AA7075, Cr is added to form $E\text{-Al}_{12}\text{Mg}_2\text{Cr}$.^[1,30] A disadvantage of these dispersoids is that they increase the quench sensitivity of the alloy. This is because the dispersoids act as potent sites for undesirable precipitation of the age-hardening elements during quenching after solution treatment.^[1] This is particularly pronounced in the case of the $E\text{-Al}_{12}\text{Mg}_2\text{Cr}$ dispersoids, which are potent nucleation sites for quench-induced precipitation due to their incoherent interface.^[8] The need to reduce quench sensitivity to tolerate slower quench rates led to a replacement of Cr and Mn with Zr as a dispersoid former in more recent 2xxx and 7xxx alloys (e.g., 2195 Al-Li, 7050). The β' - Al_3Zr dispersoids formed in such alloys have a coherent interface with the matrix (providing they are sufficiently small) and are far less potent heterogeneous nucleation sites for quench-induced precipitation. However, they are not completely inert in this regard, and the larger β' - Al_3Zr dispersoids that are typically found toward the edge of the dendrites where the Zr supersaturation is low can be potent sites for quench-induced precipitation, e.g., of η - MgZn_2 in 7050.^[33–35]

As already discussed, the nonuniform distribution of dispersoids can lead to partial recrystallization. This can be particularly pronounced in thicker section plate, where the strain imposed by rolling is insufficient to eliminate the dispersoid-free channels, which can then recrystallize during solution treatment. The result is a banded structure consisting of recrystallized and unrecrystallized regions (as shown in Fig. 1d).^[13] The high angle recrystallized grain boundaries are considered to be favorable paths for crack propagation and therefore have a detrimental effect on the toughness of the material.^[36] It is therefore desirable to eliminate the recrystallized bands, and this requires eliminating or minimizing the width of the dispersoid-free regions.

Progress toward this objective can be made by control of the heating rate to homogenization or introduction of a hold in the heating ramp to promote dispersoid nucleation in low-supersaturation regions. However, the most effective approach is to combine dispersoid-forming elements that segregate in opposite directions during solidification. As an example, the addition of small amounts of Sc in conjunction with Zr is highly effective in preventing recrystallization in 7xxx plate.^[33] During solidification, Sc segregates toward the edge of the dendrites, whilst Zr is concentrated at the center. Furthermore, both Sc and Zr can substitute into the same β' - $\text{Al}_3(\text{Zr}, \text{Sc})$ phase. This means that during homogenization, dispersoids of this phase will form more uniformly across the dendrites but will vary in composition from scandium rich at the dendrite edges to zirconium rich at the dendrite centers. Such a dispersoid distribution can completely suppress the partial recrystallization that would otherwise occur in 7xxx plate, as shown in Fig. 4.^[33]

Fig. 4 The effect of a small (0.07 wt%) scandium addition on precipitation of β' - $\text{Al}_3(\text{Zr}, \text{Sc})$ dispersoids in AA7050, and its subsequent influence on recrystallization. Without Sc (a) there is a wide dispersoid-free zone, and this leads to formation of bands of recrystallized grains after hot rolling and solution treatment. With Sc (c) the dispersoid-free zone width is greatly reduced, eliminating the recrystallized bands (d)

The disadvantage of this method is the high cost of Sc, but attempts to use an alternative dispersoid-forming element to produce the same effect (Mn) are only partially successful. This is because there is an interaction between the Mn- and Zr-containing dispersoids, that can reduce the overall pinning effectiveness and lead to an undesirable increased fraction of recrystallization.^[37,38]

SUMMARY

Controlled precipitation of a small volume fraction of stable submicron particles (dispersoids) is critical to the control of recrystallization and hence texture and properties in most wrought aluminum alloys. A number of particular features of dispersoid precipitation can be identified that strongly influence the number, size, and distribution of dispersoids formed, and hence their effect on final microstructure and properties. These may be summarized as follows:

1. Dispersoid precipitation mainly occurs during homogenization or preheat directly after casting. The dispersoids are thus precipitating from a segregated microstructure, and this typically leads to a nonuniform distribution within each grain.
2. The conditions used for homogenization or preheat are chosen to satisfy the primary objectives of these treatments and are rarely optimized for dispersoid precipitation.
3. Dispersoid nucleation is usually difficult and requires the formation of transitory precursor phases that precipitate during initial heating and then dissolve.
4. A consequence of points 2 and 3 is that dispersoid precipitation is usually very sensitive to the heating rate. By manipulating heating rate, or introducing holds during heating, dispersoids can be optimized for a specific microstructural goal.
5. In cases where dispersoids share alloying elements with constituent particles, there is often a competition for solute. During coarsening, the size advantage of the constituent particles means that they will tend to grow at the expense of dissolving nearby dispersoids.
6. A combination of dispersoid-forming elements may be preferred to compensate for the nonuniform distribution (point 1). For example, combined additions of Sc and Zr are highly effective in producing a more homogeneous distribution of β' -Al₃(Zr, Sc) dispersoids since these elements segregate in the opposite direction during solidification.

Abstract

The relationships between tensile properties and fatigue life in cast aluminum alloys have been reviewed. Strong relationships were found between fatigue life and the quality factor, Q_r , that uses tensile ductility to characterize structural quality for a number of cast aluminum alloys. The model developed by the authors to estimate the Basquin parameters as a function of Q_r is introduced along with a step-by-step guide on how to apply it to cast aluminum alloys. This model provides much more reliable estimates for cast aluminum alloys than other models available in the literature.

Keywords: Basquin law; Quality index; S-N curve; Structural integrity.

INTRODUCTION

Typically, structural components subjected to loads are designed such that maximum stresses during the lifetime of the component do not exceed the tensile yield strength of the material so that only elastic strains are developed. However, there are usually local stress concentrations due to surface imperfections, design flaws, and/or microstructural discontinuities in the structure, such as inclusions and pores. Thus, local stresses can be well in excess of the yield strength, and after some repeated loading, cracks can form and propagate until final rupture. This progressive failure is referred to as fatigue. Fatigue was originally identified as a problem in the early 1800s by engineers who observed that some bridge and railroad sections were starting to crack, although stresses were well under the yield strength. The engineers could not identify the reason for this type of failure, and thus concluded that the metal was “tired,” coining the word “fatigue”.^[1]

Today, fatigue failures are the most common failure type in service, which account for 90% of the failures reported.^[2,3] Nevertheless, there is no requirement for fatigue performance in any military or industrial specification to the authors’ knowledge. Instead, many industrial standards and specifications such as MIL-A-21180D^[4] require a number of nondestructive tests as well as tensile tests to be conducted for quality assurance purposes.

To examine properties of machined parts, there are a number of mechanical tests available to materials engineers. The most common one is the tensile test, which provides data for mechanical properties such as Young’s modulus (E), yield strength (σ_y), tensile strength (S_r), and elongation (e_f). To evaluate fatigue performance, fatigue tests need to be conducted to determine cycles to failure (N_f) at a given stress amplitude (σ_a) and mean stress (σ_m), which are usually determined based on the tensile yield strength. In fatigue test, unlike other property tests in which loads are applied gradually, specimens are subjected to alternating stresses to simulate the conditions under which the part would be in service.^[5] In high-cycle fatigue testing ($N_f > 10^5$ cycles), where the maximum stresses are well below the yield strength (as in service), it is not unusual for a single test to take days, even weeks, to produce a single data point. Consequently, fatigue testing is regarded as costly and time consuming. Conversely, the tensile test takes only several minutes to complete. There have been attempts^[6–11] to estimate fatigue properties from tensile test results. These techniques have produced mixed results for steels and wrought aluminum alloys. For cast aluminum alloys, these techniques have not produced reliable results.^[12] The present study is motivated to fill this gap in the literature and provide a framework on ductility–fatigue life relationships.

BACKGROUND

Characterization of Fatigue Test Results

Fatigue tests are run to determine the fatigue performance of materials under cyclic loading. Stress-based fatigue is one of the oldest one known to researchers, yet still being the most common type in which results are presented in Wöhler diagrams (S-N) curves in double-log or semi-log scale as stress amplitude (or maximum stress) in the y-axis and the count of resulting cycles (or reversals) to failure in another axis. In steels, there is a horizontal asymptote on their S-N diagrams that falls into approximately 10^6 – 10^7 cycles, known as the endurance limit. Such a limit is usually not observed in aluminum alloys, which is why frequently fatigue strength (as strength level corresponds to 10^6 – 10^7 cycles) is reported as their endurance limit. The change in fatigue life, N_f , with stress amplitude, σ_a , is known to follow the well-known Basquin's law:^[13]

$$\sigma_a = \sigma'_f N_f^b, \quad (1)$$

where σ'_f is the fatigue strength coefficient, and b is the Basquin exponent (also known as elastic exponent). The Basquin's law has been used to express the high cycle fatigue (HCF) behavior of metals. Both Basquin parameters are strongly affected by the material,^[14] specimen geometry^[15] as well as the type of test conducted.^[6] Because mechanical properties that involve fracture can be directly linked to casting defects, the Weibull distribution^[16–18] based on the “weakest link” theory^[19] has been used to characterize these properties. For the Weibull distribution, the cumulative probability function is expressed as

$$P = 1 - \exp \left[- \left(\frac{\sigma - \sigma_T}{\sigma_0} \right)^m \right], \quad (2)$$

where P is the probability of failure at a given stress (or fatigue life) or lower, σ_T is the threshold value below which no failure is expected, σ_0 is the scale parameter, and m is the shape parameter, alternatively known as the Weibull modulus. Note that when $\sigma_T = 0$, Eq. 2 reduces to 2-parameter Weibull distribution. The mean of the Weibull distribution is found by

$$\bar{\sigma} = \sigma_T + \sigma'_0 \Gamma \left(1 + \frac{1}{m} \right), \quad (3)$$

where Γ is the gamma function.

In HCF testing, it is common to have a combination of failure and survival data, i.e., run-outs in the same data-set. When that is the case, the data become “censored on the right tail of the distribution,” and the analysis

becomes more complex. There are several procedures to take run-outs into account during the analysis of fatigue test results.^[20–22] One such method has been recently introduced by Sarkani et al.^[20] who, with the assumption of the underlying distribution of fatigue life is Weibull, used the maximum likelihood method to estimate the coefficients in the Basquin law.

CHARACTERIZATION OF TENSILE TEST RESULTS

Tensile testing is the most commonly used test to determine the mechanical properties of metals, such as yield strength, tensile strength, and elongation. Tiryakioğlu and coworkers collected hundreds of data points from the aerospace and premium castings literature for Al-7Si-Mg, A206, and A201^[23–25] and plotted elongation versus yield strength, which is minimally affected by structural defects. They concluded that the highest elongation points form a linear trend, which can be written as

$$e_{F(\max)} = \beta_0 - \beta_1 \sigma_Y, \quad (4)$$

where β_0 and β_1 are alloy-dependent coefficients. They reported the values of β_0 and β_1 for the three alloys, which are presented in Table 1.^[24] Eq. 4 can be used to estimate the ductility potential of aluminum and magnesium alloy castings.^[24–29]

The ductility potential was proposed^[24,27,29] as a metric to determine structural quality. The quality index, Q_T , can then be found by

$$Q_T = \frac{e_F}{e_{F(\max)}} = \frac{e_F}{\beta_0 - \beta_1 \sigma_Y}. \quad (5)$$

In cast Al-7%Si-Mg alloys, Tiryakioğlu et al.^[27] observed that the tensile strength of maximum ductility points increases linearly with yield strength. Based on this observation, they proposed that maximum tensile strength, $S_{T(\max)}$, can be estimated by

$$S_{T(\max)} = 185.7 + 0.558 \sigma_Y. \quad (6)$$

Table 1 The values for coefficients β_0 and β_1 for the three aluminum alloys

	β_0 (%)	β_1 (MPa ⁻¹)
Al-7Si-Mg(-Cu)	36.0	0.064
A201	34.5	0.047
A206	47.8	0.085

THE RELATIONSHIPS BETWEEN QUALITY INDEX AND FATIGUE LIFE DISTRIBUTIONS

It was initially suggested by Wöhler that the ratio of fatigue strength to ultimate tensile strength varied between 0.4 and 0.5.^[30] Recently, it was indicated that same ratio is not a constant value but instead follows a linear trend with varying ultimate tensile strength.^[31,32] Not only ultimate tensile strength, but also yield strength and strain energy density were shown to be affecting the fatigue strength.^[31]

Tiryakioğlu^[33] analyzed previously published^[34,35] A206-T7 data. Quality index values were calculated based on the tensile test results. Subsequently, fatigue and quality index data were characterized by Weibull distribution, which is the most common statistical model for failure data. The Weibull distributions for Q_T and N_f were correlated via scanning electron microscopy as shown in Fig. 1a. The mean values of the Q_T and N_f distributions showed a linear relationship, which is shown in Fig. 1b.

Fig. 1 The relationship between structural quality and fatigue life in A206 castings:^[33] (a) correlations in Weibull distributions and (b) expected quality index–fatigue life relationship

The relationship can be written as

$$\log \bar{N}_f = 3.087 \bar{Q}_T + 4.73. \quad (7)$$

This observation led Tiryakioğlu^[33] to hypothesize that “elongation requirements in specifications are *de facto* fatigue life requirements.” This hypothesis was made by using only three data points for A206 aluminum alloy castings. To test this hypothesis, Özdeş and Tiryakioğlu^[36] followed the same approach by using more data from 319 aluminum alloy castings literature. Details of the analyses can be found in the original paper. Results showed a similar relationship as presented in Fig. 2.

The relationship for 319 aluminum alloy castings in Fig. 2 is given by

$$\log \bar{N}_f = 9.41 \bar{Q}_T + 4.93. \quad (8)$$

Similarly, the authors applied the same method to datasets of B201 and D357 aerospace castings;^[37] once again, the same trend, as presented in Fig. 3, was observed. This relationship for B201 and D357 alloy castings is given by

$$\log \bar{N}_f = 4.57 \bar{Q}_T + 1.46. \quad (9)$$

The results summarized above clearly demonstrate that there is a strong correlation between the quality index, as determined by tensile ductility, and the fatigue performance of the casting.

A METHOD TO ESTIMATE S-N CURVE OF CAST ALUMINUM ALLOYS

The promising results summarized above and their consistency led the authors to hypothesize that $\bar{Q}_T$ can be used to estimate the Basquin coefficients, i.e., the Basquin

Fig. 2 The relationship between expected (mean) quality index and fatigue life for 319 alloy castings^[36]

Fig. 3 Relationship between the means of $\bar{Q}_T$ and $\bar{N}_f$ distributions^[37,38]

exponent and the strength coefficient. This hypothesis was tested^[12] by harvesting and mostly reanalyzing S-N data from thirty-two independent studies published for Al-Si-Mg and Al-Si-Mg-Cu aluminum alloy castings. The change in the Basquin exponent, b , with $\bar{Q}_T$ is presented in Fig. 4a. The best-fit curve indicated in Fig. 4a is written as

Fig. 4 The change in (a) Basquin exponent and (b) fatigue strength-to-maximum tensile strength with the quality index

$$b = -0.136 \exp(-1.236 Q_T). \quad (10)$$

The result that the Basquin exponent is affected by the structural quality in aluminum castings is in agreement with the finding of Kun et al.^[14] who found that b is a measure of the degradation taking place at the microlevel.

The change in the ratio of fatigue strength at 10^6 cycles, σ_f to $S_{T(\max)}$ with Q_T is presented in Fig. 4b. The best-fit line can be written as

$$\frac{\sigma_f}{S_{T(\max)}} = 0.405 Q_T + 0.280. \quad (11)$$

By using Eqs. 10 and 11, the S-N curve can be estimated. The step-by-step application of the method is demonstrated below. The method was also compared in reference to six different methodologies^[6–11] available in the literature. Based on the fits to HCF data for 319 and 356 alloy castings from the literature, the new model provided^[12] much better estimates for the S-N curves of cast aluminum alloys than the six methods from the literature.

STEP-BY-STEP APPLICATION OF THE MODEL

The application of the model by the authors on the data by Zhu^[39] (E319-T7), with $\sigma_y = 199$ MPa and $e_F = 2\%$ is demonstrated below:

Step 1: Find Q_T

By inserting the yield strength and elongation data to Eq. 5, Q_T is found as

$$Q_T = \frac{2.0}{36.0 - 0.064(199)} = 0.086.$$

Step 2: Find b

By inserting Q_T to Eq. 10, we obtain

$$b = -0.136 \exp(-1.236(0.086)) = -0.122.$$

Step 3: Find $\sigma_f/S_{T(\max)}$

By inserting Q_T to Eq. 11, we obtain

$$\frac{\sigma_f}{S_{T(\max)}} = 0.405(0.086) + 0.280 = 0.314.$$

Step 4: Find $S_{T(\max)}$

By inserting $\sigma_y = 199$ MPa to Eq. 6, we obtain

$$S_{T(\max)} = 185.7 + 0.558(199) = 296.7 \text{ MPa}.$$

Step 5: Find σ_f

Combining results of Steps 3 and 4,

Fig. 5 The application of the model to the fatigue life data of 319 aluminum castings by Zhu^[39]

$$\sigma_f = 0.314(296.7) = 93.3 \text{ MPa}$$

Step 6: Find σ'_f

By rearranging the Basquin law and using the results of Steps 2 and 5, we obtain (Fig. 5)

$$\sigma'_f = \frac{93.3}{(10^6)^{-0.122}} = 505.4 \text{ MPa}.$$

CONCLUSIONS

- There is strong evidence in the literature for multiple cast aluminum alloys that there is a strong relationship between the structural quality, as determined by tensile elongation, and fatigue life.
- The elongation requirement in industrial and military specifications on aluminum castings is indeed a *de facto* fatigue life requirement.
- The structural quality, Q_T can be used to estimate the Basquin parameters, which is consistent with the physical meaning of the Basquin exponent as described by Kun et al.
- The methodology to estimate the S-N curve from Q_T has been demonstrated to provide better fits to data from aluminum casting than other models in the literature.

Electrical Conductivity of Aluminum Alloy A2011

Sayavur Bakhtiyarov

Mechanical Engineering, New Mexico Institute of Mining and Technology, Socorro, United States

Ruel Overfelt

Mechanical Engineering, Auburn University, Auburn, AL, 36801, United States

Abstract

A rotational, contactless inductive measurement technique has been used to determine the effect of pores and metallic insertions on the electrical resistivity of A2011 aluminum alloy at different temperatures. It is shown that the electrical resistivity increases with the total volume of pores and is also dependent on the pores locations and orientation. Additional energy losses were found on the contact surfaces between sample and insertions.

Keywords: Aluminum alloy; Electrical resistivity; Porosity; Thermal conductivity.

INTRODUCTION

Information on the electrical resistivity of molten alloys is especially important in many metallurgical processes such as electroslug remelting, electromagnetic stirring in continuous casting, and induction melting in foundries. The electrical resistivity of the metals and alloys in both solid and liquid phases is affected by the porosity formations and some immiscible inclusions. From a practical point of view, it is crucial to know the variation of the electrical resistivity with the pores and inclusions. However, there are no studies reported in this area. Electromagnetic detection methods such as eddy current, magnetic particle, ultrasonic, etc., introduce electromagnetic or sound waves into the specimen to detect its properties. Eddy current testing allows also crack detection for both ferromagnetic and non-ferromagnetic materials, when other nondestructive techniques (e.g., the magnetic particle method) are limited to ferromagnetic metals. The second advantage of the eddy current method over other techniques is that inspection can be performed without any direct physical contact between the sensor and the specimen.

Recently, Bakhtiyarov and Overfelt^[1,2] developed a rotational, contactless, inductive measurement technique to measure both the viscosity and the electrical conductivity of metals and alloys over wide ranges of temperatures. Preliminary tests conducted with low-melting-point metals (lead and tin) and alloys (LMA-158 and Pb/Sn binary systems) showed a good agreement with data from the literature. This technique requires a reliable relationship between the electrical resistivity of the metal sample and the measured damping torque values. Braunbeck^[3] proposed the following relationship between the opposing

mechanical torque (T) and the electric conductivity of a rotating liquid specimen (σ_e) in a DC external magnetic field of induction B :

$$T = \frac{\pi}{4} \sigma_e \omega L R^4 B^2 - \frac{\pi}{192} \frac{1}{\eta} \sigma_e^2 \omega L R^6 B^4, \quad (1)$$

where L and R are the length and radius of the specimen, respectively, ω is the angular velocity of the rotating magnetic field, and η is the viscosity of the liquid specimen. The magnetic induction and the radius of the specimen can be selected so that the second term in Equation 1 will become negligibly small compared with the first term for measurements on metals with unknown viscosity.^[4]

The objective of this article is to study the effect of porosity formations and non-ferrous inclusions on the electrical resistivity of A2011 aluminum alloy obtained by direct measurements using the rotational technique (with a cylindrical metal sample rotating in a 2-pole DC magnetic field) over wide ranges of temperatures.

EXPERIMENTAL APPARATUS AND PROCEDURES

A schematic of the experimental apparatus to measure an electrical resistivity of metals and alloys over a wide range of temperatures is shown in Fig. 1. A computer-controlled Brookfield rheometer, Model DV-III, was used to provide a constant rotational speed to the metal sample and to measure the torque. This rheometer enables torque measurements from 0 to 673.7 dyne-cm at constant speeds from 0

Fig. 1 Experimental apparatus used for electrical resistivity measurements of solid and molten metals

to 250 RPM in 0.1 RPM increments. The rheometer has an RS232 serial port for communication with a local computer.

The temperature of the sample was characterized remotely by a portable 2-color infrared thermometer M90 (Mikron®) focused into a hole in the bottom of the crucible assembly since thermocouple leads could not be inserted into the rotating samples. Focusing into the hole in the crucible bottom eliminated spurious temperature data from extraneous reflections into the infrared thermometer from the optical heaters. The infrared thermometer output was calibrated to actual temperature by comparing against thermocouple data using a dummy load with 0.25% accuracy. The thermometer output was connected to a computer, and the temperature data obtained were synchronized with data for measured torque and angular velocity of the crucible.

Metal samples (19.05 mm diameter and 38.1 mm length) for testing were inserted into cylindrical high-purity alumina crucibles with a flat bottom. The extruded alumina crucibles (19.05 mm inner diameter and 152.4 mm length) were attached to the spindle of the rheometer through a specially designed coupler to provide concentricity to the rotating shaft, crucible, and sample. The same sample diameter was maintained for each set of tests. The rotational technique of this geometry is exposed to the end effects in the crucible. This effect was eliminated from the results of two experiments accomplished with the different heights (25.4 and 38.1 mm) of the sample in the crucible at the same angular speed.

Two quartz infrared line heating elements (2kW each) housed in elliptical cast aluminum frames were used to heat the samples in the experiments. The heated length of the chamber was 167 mm. The elliptical reflectors concentrated the infrared energy to the crucible surface (Fig. 2). Copper tube connections are provided for inlet and outlet flow of water to cool the lamp reflector bodies. Tap water at 15°C and 600kPa was supplied to cool the unit.

The magnetic field was produced by two neodymium-iron permanent magnets. A Hall-effect gaussmeter was used to measure the magnetic field strength. The gaussmeter provides DC and AC field readings from $\pm 10^{-5}$ to ± 2 Tesla with 0.1% resolution. Changing the separation between the magnets allowed us to obtain magnetic fields of different magnitudes. Contour mapping of the magnetic field strength revealed that the magnetic induction varies in both vertical and horizontal directions. It is estimated that the magnetic induction over the test sample varies $\pm 10\%$ in vertical direction and $\pm 7\%$ in horizontal direction compared to its average value. Neither the coupling system nor the alumina crucible had measurable effects upon the applied magnetic field.

RESULTS AND DISCUSSION

As a test sample, we used A2011 aluminum alloys (Si—0.4%, Fe—0.7%, Cu—6%, Zn—0.3%) popular in commercial applications. Two sets of experiments were conducted

Fig. 2 Diagram of sample magnetic field optical furnace arrangement and heating energy focus action

in this study. In the first set of experiments, the cylindrical holes of 2.08 mm diameter were drilled through the samples in longitudinal or traversal directions to study the influence of the orientation of porosity formations on the electrical resistivity measurements. In the second set of experiments, a longitudinal cylindrical hole of 4.00 mm diameter was drilled through the sample. The orientation and total volume of holes are presented in Table 1. The experiments were conducted with pores, as well as with the pores filled by conductive material (A2011 alloy, In or Cu).

The experimental results were compared with the simulations based on the mass amount of each component. Electrical resistivity of the two-component sample was estimated by the following expression:

$$\rho_{1+2} = \frac{\rho_1 C_1}{100} + \frac{\rho_2 C_2}{100}, \tag{2}$$

where ρ_1 and ρ_2 are electrical resistivity of components “1” and “2”, respectively; C_1 and C_2 are mass concentration of components “1” and “2”, respectively.

Table 1 Orientation and total volume of pores

Orientation of pores	Diameter of each pore, cm	Volume of sample, cm ³	Total volume of pores, cm ³	Porosity
None	0	10.85387	0	0
Longitudinal	0.208		0.1294	0.011922
			0.3882	0.035766
			0.6470	0.05961
Transverse			0.1294	0.011922
			0.3882	0.035766
			0.6470	0.05961
Longitudinal	0.400		0.4785	0.044089

Electrical resistivity of the material at the solid state as a function of temperature was determined as follows:

$$\rho_{T_2} = \rho_{T_1} [1 + \alpha (T_2 - T_1)], \tag{3}$$

where ρ_{T_1} and ρ_{T_2} are electrical resistivity at temperatures T_1 and T_2 , respectively; α is a temperature coefficient of electrical resistivity.

For materials in the liquid state, the electrical resistivity varies with temperature according to the following formula:

$$\rho_e = \alpha T + \beta, \tag{4}$$

where α and β are temperature coefficients for liquid metals and T is an absolute temperature in K. The temperature coefficients were experimentally determined for tested materials (Table 2).

Figure 3 shows a variation of the eddy-current-induced damping torque values with different oriented pores for A2011 alloy at $T = 23^\circ\text{C}$, $B = 0.1$ T, and $\omega = 1.05$ s⁻¹. As expected, the damping torque decreases with porosity in the sample. However, the torque values are slightly (up to 8%) higher for longitudinally oriented holes than

Table 2 Temperature coefficients of test materials

Material	State	α (1/°C)	α (μΩ cm K ⁻¹)	β (μΩ cm)
A2011 alloy	Solid	0.00394	0.0145	10.7
	Liquid	—	0.0145	10.7
Indium	Solid	0.004331	—	—
	Liquid	0.000802	0.0255	22.2
Copper	Solid	0.00381	—	—
	Liquid	—	0.0089	9.1

Fig. 3 Variation of torque with porosity of different orientation for A2011 alloy at $T = 23^\circ\text{C}$, $B = 0.1\text{ T}$, and $\omega = 1.05\text{ s}^{-1}$

for transversely oriented ones. One would assume that in a magnetic field, induced circulating eddy currents, which generate an opposing torque, are weakened more by transversal holes than by longitudinal ones. Using formula (3), we estimated the electrical conductivity (reciprocal of the electrical resistivity) of the samples, and the results are presented in Fig. 4. As seen from this figure, the measured values of the electrical conductivity are significantly lower (up to 17%) than those predicted. However, the simulations do not consider distribution and orientation of the pores. Hence, we can conclude that the pores' distribution and orientation is an important factor, and any future theoretical model must take this into account.

As we know, free electrons are responsible for the electrical and thermal conductivities of metals and alloys in both solid and liquid states. Therefore, the Wiedemann-Franz-Lorenz law can be applied to relate the thermal conductivity to the electrical resistivity:

$$\frac{\lambda \rho_e}{T} = \frac{\pi \kappa^2}{3 e^2} \equiv L_0, L_0 = \frac{\pi^2 \kappa^2}{3 e^2} = 2.45 \times 10^{-8} \text{ W } \Omega \text{ K}^{-2}, \quad (5)$$

where κ is the Boltzman constant, e is the electron charge, and the constant L_0 is the Lorenz number. The validity of this relationship has been confirmed experimentally with high accuracy by many researchers.^[5-8] A variation of the thermal conductivity estimated by

Fig. 4 Variation of electrical conductivity of A2011 alloy with porosity of different orientation at $T = 23^\circ\text{C}$, $B = 0.1\text{ T}$, and $\omega = 1.05\text{ s}^{-1}$

Fig. 5 Variation of thermal conductivity of A2011 alloy with porosity of different orientation at $T = 23^\circ\text{C}$, $B = 0.1\text{ T}$, and $\omega = 1.05\text{ s}^{-1}$

the Wiedemann-Franz-Lorenz law against porosity of different orientation is presented in Fig. 5.

The variations of the electrical resistivity and thermal conductivity of A2011 sample with 4 mm diameter longitudinal hole ($\phi = 0.0441$) versus temperature are shown in Figs. 6 and 7, respectively. As seen from Fig. 6, electrical resistivity increases almost linearly with temperature. There is good agreement between experimental results and prediction by formula (3).

It is of practical and scientific interest to study the electrical resistivity of immiscible alloys. In this article, we also measured the electrical resistivity of A2011 aluminum

alloy with pores filled by indium, A2011 aluminum alloy itself, and copper.

Figures 8 and 9 represent the experimental values of the electrical resistivity and thermal conductivity over the wide ranges of temperatures for A2011 aluminum alloy sample with 4 mm diameter longitudinal hole ($\phi = 0.0441$) filled by indium. The results of simulations for a sample with pores hole and for holes filled by indium also presented in these figures. As seen from Fig. 8, the electrical resistivity for a sample filled by indium is lower than for a sample with pores. Due to the phase transformation in indium at $\sim 150^\circ\text{C}$ (from solid state to liquid), a significant

Fig. 6 Variation of electrical resistivity of A2011 alloy (with 4 mm hole) with temperature at $\phi = 0.0441$, $B = 0.1\text{ T}$, and $\omega = 1.05\text{ s}^{-1}$

Fig. 7 Variation of thermal conductivity of A2011 alloy (with 4 mm hole) with temperature at $\phi = 0.0441$, $B = 0.1$ T, and $\omega = 1.05$ s⁻¹

Fig. 8 Variation of electrical resistivity of A2011 alloy (with and without Indium inclusion) with temperature at $\phi = 0.05961$, $B = 0.1$ T, and $\omega = 1.05$ s⁻¹

increase in electrical resistivity is observed. Again, the experimental data are lower than those predicted by formula (2), which can be attributed to the effect of the location and orientation of the indium inclusion in the A2011 sample.

One would expect that if the pores were filled by the same material as the sample A2011 aluminum alloy, the electrical resistivity will be recovered to its original value for a sample without pores. However, the experiments reveal that the electrical resistivity for samples with holes filled by the same type of metal is higher than the electrical

resistivity of the original sample. We would suggest that there are additional energy losses on the contact surfaces. The variations of the electrical resistivity and thermal conductivity of A2011 sample with the longitudinal hole ($\phi = 0.0441$) filled by the same metal (A2011) versus temperature are shown in Figs. 10 and 11, respectively.

Figures 12 and 13 show the variations of the electrical resistivity and thermal conductivity over the wide ranges of temperatures for A2011 aluminum alloy sample with 4 mm diameter longitudinal hole ($\phi = 0.0441$) filled by copper. As seen from Fig. 12, the electrical resistivity for

Fig. 9 Variation of thermal conductivity of A2011 alloy (with and without Indium inclusion) with temperature at $\phi = 0.05961$, $B = 0.1$ T, and $\omega = 1.05$ s⁻¹

Fig. 10 Variation of electrical resistivity of A2011 alloy (with 4 mm hole filled by A2011) with temperature at $\phi = 0.0441$, $B = 0.1$ T, and $\omega = 1.05$ s⁻¹

Fig. 11 Variation of thermal conductivity of A2011 alloy (with 4 mm hole filled by A2011) with temperature at $\phi = 0.0441$, $B = 0.1$ T, and $\omega = 1.05$ s⁻¹

Fig. 12 Variation of electrical resistivity of A2011 alloy (with 4 mm hole filled by Cu) with temperature at $\phi = 0.0441$, $B = 0.1$ T, and $\omega = 1.05$ s⁻¹

Fig. 13 Variation of thermal conductivity of A2011 alloy (with 4 mm hole filled by Cu) with temperature at $\phi = 0.0441$, $B = 0.1$ T, and $\omega = 1.05$ s⁻¹

sample filled by copper is higher than predictions made by formula (2). This can again be attributed to the effect of the location and orientation of the copper insertion and the additional energy losses on the contact surfaces.

CONCLUSIONS

A simple rotational technique to measure the electrical resistivity of molten metals has been applied to study the effect of the porosity formations and different metallic insertions in pure A2011 aluminum alloy. The experimental results revealed the effect of the location and orientation of

pores and metallic insertions. Additional energy losses on the contact surfaces resulted in higher electrical resistivity of samples with insertions compared to predictions.

Electrical Resistivity of Al-Cast Alloys in the Range of Solidification

Mitja Petric, Jožef Medved, Sebastjan Kastelic, Maja Vončina, and Primož Mrvar

Department of Materials and Metallurgy, University of Ljubljana, Aškerčeva 12, Ljubljana, 1000, Slovenia

Abstract

The aim of this paper is to explain the electrical resistivity change during solidification and connect it with the thermal analysis and solidification course. The problem at conducting the “in situ” measurement by four-point technique is the electrode material, which often oxidizes during measurements causing high contact resistance and providing incorrect results. Various materials were tested and aluminum electrodes chosen. The advantage of aluminum electrodes is that they melt within the specimen immediately after being poured and cause no interface resulting with any contact resistance. Pure aluminum, hypoeutectic alloy AlSi7Mg, and eutectic AlSi12 alloys were tested. Resistivity of Al–Si alloys is increasing with Si content. Grain refinement and modification of β_{Si} were employed. Grain refinement has any effect on electrical resistivity. Modification of β_{Si} phase causes decrease of electrical resistivity. The electrical resistivity curves give information similar as cooling curves from thermal analysis measurements.

Keywords: Al–Si alloys; Electrical resistivity; Electrode material; Grain refinement; Modification; Solidification.

INTRODUCTION

Several methods exist for characterization of solidification of metal materials using thermal analysis, metallographic analysis, dilatometry, and electrical resistivity measurement described in literature.^[1–3]

Electrical resistivity measurement is a commonly used method for material characterization. There are several different methods used for measuring electrical resistivity within molten metals, such as inductive techniques, the rotary magnetic field method,^[4–6] the two-probe method, and the most used four-probe DC method. The four-probe DC method has the advantage of eliminating the measurement of wires’ resistivities and is used for measuring small resistivity. In order to eliminate thermoelectric effects on contacts between electrodes and the sample, the current with very low frequency square wave^[7] or bidirectional current^[8,9] is used.

Measuring electrical resistivity within a solid state using a four-probe DC method is not that problematic in terms of measuring cell and contact materials since there are less reactions between the electrode material and the sample at lower temperatures.^[10–14] Measurement within a liquid state and during solidification, however, can

cause several problems because the metal must be held in a measuring cell and the electrode material selected in a manner that achieves good contact and prevents reactions with the melt and oxidation. Oxidized electrodes can cause high contact resistance leading to incorrect results. Dissolved electrodes in liquid metal can change the chemical composition of a sample that is influencing electrical resistivity and pour wetting between the electrode and the melt again negatively influences contact resistance, so the wetting should be good.^[8] Different authors have used electrodes of several materials, such as tungsten, platinum, molybdenum, graphite, and high-alloyed stainless steel and nickel^[7–9,15–17] for measuring electrical resistivity of different metals. In case of aluminum and aluminum alloys, they used tungsten,^[17] graphite,^[15] and stainless steel^[16] electrodes.

Different kinds of thermal analyses can be employed at solidification course study for different materials. One of the most commonly used is simple thermal analysis, where the temperature of a sample is measured during solidification. From obtained cooling curve, characteristic temperatures such as liquidus temperatures (T_L), eutectic temperatures (T_E), and solidus temperatures (T_S) can be seen, which describe the solidification course of an alloy.

The state of the microstructure can be predicted to some degree in terms of grain size and shape and size of eutectic phases from undercooling and recalescence.

The possibility to describe the solidification course and the state of microstructure of the Al-cast alloys by the “in situ” measurement of electrical resistivity is described in the paper. It was reported^[18] that modification of eutectic in Al–Si alloys influences the electrical resistivity since the size and shape of eutectic β_{Si} particles is changed.

EXPERIMENTAL

Electrodes that were tested were made from nickel, molybdenum, copper, aluminum, and graphite. At testing different electrode materials, the pure aluminum and AlSi9Cu3 alloy were used. Temperature was measured with K-type thermocouple. Four-probe DC technique was used to measure electrical resistivity as described in literature.^[19] A measuring cell was produced from calcium-silicate brick which does not conduct electrical current which is essential at measuring electrical resistivity of metals. A measuring cell was used permanently since it was not damaged at casting ejection.

Electrical resistivity measurements in order to determine solidification course were performed on 99.9 wt% pure aluminum and aluminum silicon alloys such as AlSi7Mg and AlSi12 where the melt was gravity casted into the measuring cell at approximately 820°C and let to cool until about 50°C. During cooling, the temperature and electrical resistivity were measured continuously. The aluminum, AlSi7Mg, and AlSi12 alloys were grain refined with Ti addition by master alloy AlTi5B1, and the alloys were modified by the addition of Sr by master alloy AlSr10 in order to achieve smaller and rounded particles of eutectic silicon. In addition, both alloys were grain refined and modified in the same time to observe the effect of both additions to the melt. Chemical compositions of alloys and amount of additions are presented in Table 1. Measurements were performed in a measuring cell described in literature.^[19]

Contacts between the electrodes and the samples and microstructures were analyzed by optic metallography using Olympus BX 61 microscope and scanning electron microscopy (SEM) in JEOL JSM-5610. Chemical composition of phases was determined by energy-dispersive spectroscopy (EDS).

RESULTS AND DISCUSSION

Analyses of Electrodes

At testing of different electrode materials, the graphite, Ni, and Mo showed negative results. The electrical resistivity of casting was rising during complete measurement, which is not the case of theory as described in literature.^[15,20] Reason for increasing resistivity was oxidation of electrodes because of high temperatures. The oxide layer was causing an increase in contact resistance and was increasing electrical resistivity of sample during measurement. Figure 1 is showing contact of Ni electrode in AlSi9Cu3 alloy where dark thin film represents oxide between electrode and sample. It was confirmed by line EDS analysis presented in Fig. 1c, line of EDS is marked in Fig. 1b. In the case of graphite bar, the contact between the electrode and sample was interrupted due to shrinkage of casting during solidification and cooling. In the same time, it was hard to implement all four electrodes into one measuring cell.

When Cu electrodes were tested, it was obvious right after measurement that Cu was dissolved in aluminum sample since Cu wires had silver color on the surface near the sample and were immediately broken off because of brittleness since Al diffused into the Cu. Metallographic analysis of Al sample with Cu wires is shown in Fig. 2a where Cu phase $Al_2Cu-\theta$ (according to literature^[21]) is seen in the area of contact. Also area of Cu wire is marked in figure but it was mostly dissolved in Al sample. From these findings, we can see that the contact between wire and sample was eliminated by fusing Cu wire with Al sample, consequently eliminating contact resistance, too, but the problem is newly formed $Al_2Cu-\theta$ phase and dissolved Cu atoms in Al melt, which contaminate the sample and cause higher electrical resistivity of sample. In order not to contaminate the sample with impurities, Al wires were used, which are similar as Cu wires molten and dissolved into the specimen and are eliminating the contact resistance. Metallographic investigation of samples using Al wires is presented in Fig. 2a,b where positions of wires are marked. It can be seen that the outer surface of Al wire is not totally molten but the inner part of wire is well fused with sample. Such contact of Al wire with sample of pure Al or Al alloy is ideal because the contact resistance is eliminated and sample is not contaminated with impurity atoms. In further measurements, the Al wires were used as an electrode material.

Table 1 Chemical compositions of tested alloys and additions of master alloys

Alloy	Element (wt%)									AlTi5B1 and AlSr10 additions	
	Al	Si	Fe	Cu	Mn	Mg	Zn	Ti	Rest	Ti (wt%)	Sr (wt%)
Al	99.88	0.03	0.05	—	—	—	—	—	0.04	0.06	—

Solidification and Electrical Resistivity

The result of electrical resistivity measurement of pure Al sample is completely comparable to results of Brandt and Neuer,^[15] which is confirming the accuracy of a measuring cell and a device. In addition, measurements of electrical resistivity were performed on grain-refined sample of pure aluminum shown in Fig. 3.

Solidification path is described by the cooling curve where at 658.1°C (T_L) α_{Al} phase starts to precipitate

Fig. 2 Optic micrograph of Al sample with Cu wire (a), Al sample with Al wire (b), and AlSi9Cu3 sample and Al wire (c)

followed by the eutectic ($\alpha_{Al} + Al_{13}Fe_4$) solidification at 652.0°C. Solidification ends at T_s at 616.6°C. Microstructure of Al sample is presented in Fig. 4. Characteristic temperatures are marked by vertical lines in Fig. 3a, which is presenting analysis of cooling curve with its derivative curve and electrical resistivity curve with its derivative curve. It is clear that characteristic points on the cooling curve and derivative cooling curve such as T_L , T_E , and T_s coincide perfectly with inflection points

Fig. 3 Cooling and its derivative curve and electrical resistivity and its derivative curve with base line (a) and electrical resistivity curves of pure Al sample and grain-refined Al sample, respectively (b)

Fig. 4 SEM microstructure of Al sample with marked phases determined by EDS analysis

on electrical resistivity curve and derivative electrical resistivity curve. Figure 3b is showing electrical resistivity dependent on temperature, and one can see that after liquidus temperature is reached, the electrical resistivity is drastically descended until solidus temperature is reached than the electrical resistivity is linearly decreasing till the room temperature. Grain refining of Al sample by Ti addition shows no difference in electrical resistivity, which means that lower grain size has any big effect on electrical resistivity of pure Al.

Solidification of AlSi7Mg alloy was investigated in the same manner as pure Al. From Fig. 5a, one can see the cooling curve that is showing basic characteristic temperatures determining the solidification path. First, the solidification of α_{Al} phase is taking place at T_L followed by eutectic ($\alpha_{\text{Al}} + \beta_{\text{Si}} + \beta\text{-AlFeSi}$) at T_E . At the last interval of solidification, two more eutectics appear containing

Fig. 5 Cooling and its derivative curve and electrical resistivity and its derivative curve with base line for AlSi7Mg alloy (a) and electrical resistivity curves of AlSi7Mg alloy with addition of Ti and Sr (b)

Mg_2Si phase and $\pi\text{-AlMgFeSi}$ phase. The last two phases are nonequilibrium phases that are discussed in literature.^[21,22–24] Figure 6 is presenting microstructures with marked phases of AlSi7Mg alloy and AlSi7Mg alloy with addition of Ti and Sr. Modified microstructure is evidently finer where particles of β_{Si} are finer than in unmodified where average surface of a particle is reduced for about 93%.

The electrical resistivity curve is showing similar correlation with the cooling curve as in case of Al sample. The inflection points on derivative cooling and derivative resistivity curves coincide perfectly from which can be concluded that the solidification path can be recorded by electrical resistivity measurements. Figure 5b is presenting electrical resistivity of all four samples from AlSi7Mg alloy with additions of Ti, Sr, and both together. No big differences in electrical resistivity of all samples can be observed meaning that grain refinement and modification has no big effect at the alloys with lower content of Si. As stated in literature,^[25] the electrical resistivity of

alloys with up to 6 wt% Si is not sensitive to modification since the conductivity of an alloy is mainly dependent on the conductivity of α_{Al} phase.

Solidification of AlSi12 alloy takes place starting with α_{Al} phase. In the same time, the $\text{Al}_9\text{Fe}_2\text{Si}_2$ phase should precipitate. At the eutectic temperature, the main eutectic ($\alpha_{\text{Al}} + \beta_{\text{Si}}$) is solidifying, and at the end of the solidification, the eutectic $\text{Al}_{14}(\text{Fe},\text{Mn})_4(\text{Al},\text{Si})_5$ phase appears determined by EDS analysis and by literature.^[24,26] The cooling curve of AlSi12 sample is presented in Fig. 7a.

In case of AlSi12 alloy, we can see similar phenomena on cooling and electrical resistivity curves and their derivatives as in case of pure Al and AlSi7Mg alloy. It is seen that phenomenon on curve of electrical resistivity coincides with phenomenon on cooling curves (Fig. 7a). One can easily determine the start of solidification and the end of solidification from the electrical resistivity curve. The start of solidification with α_{Al} phase solidification is observed when the derivative electrical resistivity curve is separated from basic curve and decreases. During solidification of α_{Al}

Fig. 6 Microstructure of AlSi7Mg alloy: microstructural constituents (a), sample without additions (b), and sample with addition of Ti and Sr (c)

phase, the derivative electrical resistivity curve approaches back to base line and separates again after primary crystallization is finished. The derivative electrical resistivity curve decrease suggests on eutectic solidification. At the end of solidification, the derivative electrical resistivity curve increases back to base line determining the T_s .

The drop of electrical resistivity is bigger at solidification of primary α_{Al} grains. Figure 7b is showing the comparison of electrical resistivity curves of AlSi12 sample with addition of Ti and Sr. It is obvious that the curves of AlSi12 alloy and grain refined by Ti alloy are nearly identical, which confirms statement that the grain refinement has little effect on electrical resistivity. In case of Sr-modified samples, there are some differences especially in eutectic area of the curves. One can see that the electrical resistivity is lowered in this area of solidification especially for the sample with addition of Sr where modification effect is the best (Fig. 8c). In the sample with both additions, Ti and Sr, the modification effect is lower due to interaction of Ti and Sr.^[27,28] Reasons for such phenomena are smaller and more rounder solidified particles of β_{Si} , which cause less electron scattering resulting in lower electrical resistivity as

Fig. 7 Cooling and its derivative curve and electrical resistivity and its derivative curve with base line for AlSi12 alloy (a) and electrical resistivity curves of AlSi12 alloy with additions of Ti and Sr (b)

Fig. 8 Microstructure of AlSi12 alloy: microstructural constituents (a), sample without additions (b), and sample with addition of Sr (c)

described in Refs. [18,25,29–32,33]. After the end of solidification, the electrical resistivity is linearly decreasing with temperature.

Figures 3, 5, and 7 are showing that the electrical resistivity of pure aluminum is lower than one from AlSi7Mg and AlSi12 alloys which makes aluminum better conductor. Reasons for higher resistivity of AlSi7Mg and AlSi12 alloy are the presence and quantity of different phases in microstructure formed during solidification such as β_{Si} , Mg_2Si , $Al_9Fe_2Si_2$, and $Al_{14}(Fe,Mn)_4(Al,Si)_5$, which are causing electron scattering and β_{Si} and Mg_2Si phases are even semiconductors. Also traces of elements dissolved in α_{Al} phase negatively influence electrical resistivity of alloys.^[33]

CONCLUSIONS

The electrode material for measuring electrical resistivity of Al and its alloys in molten state and during solidification was chosen as aluminum since it causes no oxidation of electrodes and no contamination of sample with foreign atoms. At the same time, the electrode is fused with the sample, which is eliminating contact resistance.

It is clear that alloying elements in the Al alloys negatively influence on the resistivity of alloys. The amount of phases, especially β_{Si} , in microstructure causes an increase in electrical resistivity. Alloying elements dissolved in α_{Al} grains also cause higher electrical resistivity.

Modification of eutectic β_{Si} decreases electrical resistivity of the AlSi12 alloy due to smaller and rounder particles of β_{Si} phase uniformly solidified in microstructure which can be detected already during solidification. The grain refinement and modification has nearly no effect on electrical resistivity of AlSi7Mg alloy since amount of β_{Si} phase is relatively low and the α_{Al} is main conducting phase in the alloy.

Characteristic temperatures during solidification are recorded on both the electrical resistivity curve and cooling curve and coincide perfectly. The solidification path can be described by the electrical resistivity measurements, and the state of the microstructure predicted to some extent.

Electrochemical Study of Potassium Fluoride in a Cryolite-Aluminum Oxide Molten Salt

Shaohu Tao, Jianping Peng, Yuezhong Di, Kejia Liu, Kun Zhao,
and Naixiang Feng

School of Metallurgy and Materials, Northeastern University, Shenyang, China

Abstract

Selective and efficient electrochemical methods to characterize aluminum are necessary. Current methods are based on potentiodynamic polarization, recurrent potential double pulses, chronopotentiometry, open-circuit chronopotentiometry, and potentiostatic electrolysis, but have not been used to characterize the deposition of aluminum in $\text{Na}_3\text{AlF}_6\text{-Al}_2\text{O}_3\text{-KF}$ molten salts. The control processes of the formation of aluminum-tungsten inter-metallic compounds, and the deposition of aluminum have been investigated by using steady-state potentiodynamic cathodic polarization curves. The dissolution loss rate of aluminum was determined with an increase in KF concentration by the analysis of recurrent potential double pulses. Using chronopotentiometry, it was confirmed that the deposition potential of aluminum shifted more negative as the KF concentration increased, and a higher KF concentrations induced a higher cathodic overpotential. From open-circuit potential measurements and scanning electron micrographs, it was concluded that aluminum(III) ions react with tungsten substrates to form an aluminum-tungsten compound, and the reaction mechanism of aluminum was determined. These electrochemical methods applied with aluminum electrolysis were accurate, efficient, and reliable.

Keywords: Aluminum electrolysis; Cathodic electrochemistry; Electrolytes; KF; Process control.

INTRODUCTION

It has been over 120 years since cryolite-aluminum oxide-based melts were first used for aluminum electrolysis by Hall and Heroult in 1886.^[1] As aluminum electrolysis has matured, the technique has improved considerably. The current strength has increased from a few thousand amperes to 500–600 kA and current efficiency has greatly increased. However, there are still several questions to be clarified involving the basic principles of aluminum electrolysis: for example, the kinetics of electrode reactions and the mechanism following the addition of ionic compounds and other additives.^[2–4]

In aluminum electrolysis, cryolite and aluminum oxide are the principal raw materials. In order to increase current efficiency and also improve the conductivity and other electrolyte properties, alkali metal fluorides, and alkaline earth fluorides are added to the electrolyte.^[5,6] Due to the high concentrations of lithium and potassium in local aluminum oxide in China, high concentrations of LiF and KF are enriched in electrolytic cells.^[7–11] As a result, the electrolyte composition is unknown, which may influence the carbon cathode. In particular, KF is undesirable in the

melt due to formation of potassium metal that may damage to the cathode.^[12,13] The erosion of the carbon cathode has been previously studied in the presence of potassium additives,^[14] demonstrating that potassium may be incorporated into the carbon, causing its expansion.^[15] reported that the decomposition of carbon induced by potassium compounds was affected by temperature. However, low KF concentrations may improve the dissolution rate of aluminum oxide, and reduce the temperature of the liquid electrolyte and the current efficiency.^[16–18] Various KF concentrations are present in aluminum processing, suggesting that low levels are acceptable. Many reports^[19–23] are focused on low temperature electrolyte systems, but it is difficult to apply this work to industrial processes. Our research focuses on the improvement of aluminum electrolysis.

The influence of KF on electrode reactions has not been commonly investigated in the literature in cryolite-aluminum oxide molten salts, in spite of its significance. Consequently, work should be focused in the area. Several papers^[24–28] investigated current efficiency and aluminum dissolution losses by cyclic voltammetry and chronopotentiometry, and introduced theoretical principles for aluminum electrolysis. However, most previous studies focused

on the cryolite-aluminum oxide employing single electrochemical measurements. Therefore, innovative electrochemical methods are required for aluminum electrolysis with updated theoretical principles.

This goal of this paper is to provide a better understanding of the influence of KF concentration on electrochemical behavior during aluminum electrolysis at a tungsten electrode. Potentiodynamic polarization, recurrent potential double pulse, chronopotentiometry, open-circuit chronopotentiometry, and potentiostatic electrolysis were employed to characterize this molten salt system.

EXPERIMENTAL

The cell consisted of a corundum crucible with a 15-mm hole in the bottom in a graphite crucible, which is fitted in a stainless steel crucible. All crucibles were placed in a refractory steel cylindrical vessel with a stainless steel lid cooled by the circulation of water. Experiments were performed under an argon atmosphere (U-grade: less than 5 ppm O_2) that was dehydrated and deoxygenated using a purification cartridge (Air Liquide). The cell was heated using a programmable furnace and the temperature was measured by a thermocouple.

The electrolytic bath consisted of an eutectic Na_3AlF_6 - Al_2O_3 mixture at various concentrations of KF, 0, 1, 3, 5, 7% (wt. %) and a cryolite ratio (CR) of 2.5. Before use, anhydrous KF was dried at 523 K under vacuum for 12 h. AlF_3 was pre-treated by heating at 473 K for 5 h and at 773 K for 6 h. After pretreatment, all reagents were homogeneously mixed in a glove box by continuous grinding. The mixture (150 g) was transferred to a corundum crucible in a graphite crucible, which was heated in a flow of argon to the working temperature.

Tungsten wires (2 mm diameter) were used as working electrodes ($A = 1 \text{ cm}^2$). Prior to electrochemical measurements, the tungsten electrodes were polished by Emery paper with increasingly fine grades, followed by polishing with aluminum oxide (0.05 μm). The surface area of the working electrode was measured after withdrawal from the cell. The auxiliary electrode was a stainless crucible with a large surface area. All potentials were measured with respect to a tungsten wire immersed in the molten electrolyte, who acted as the reference electrode.

All electrochemical studies were performed with a Parstat 2273 potentiostat/ galvanostat and a Kepco bipolar operational power amplifier (Booster 20 A) under computer control using the Powersuite software. Data were fitted by Origin 8.0 software.

Potentiodynamic polarization, recurrent potential double pulses, chronopotentiometry, open-circuit chronopotentiometry, and potentiostatic electrolysis were used for the investigation of the aluminum reduction process.

After electrolysis, the cathode surface was examined by scanning electron microscopy (SEM) (Hitachi-SU8010).

RESULTS AND DISCUSSION

Potentiodynamic Polarization Curves

Potentiodynamic cathodic polarization measurements were employed to investigate the cathodic control process during deposition of aluminum metal. The response current of the electrode was measured as a function of potential. The following parameters were employed: a cryolite ratio of 2.5, scan rate of 5 mV/s, a scan potential range of -0.1 V to -1.5 V versus the reference, working electrode area of 1 cm, a temperature of 1253 K, and 3% (wt) Al_2O_3 . Figure 1 shows potentiodynamic cathodic polarization curves at the tungsten electrode in Na_3AlF_6 - Al_2O_3 as a function of KF concentration. For the cathodic process, a plateau was observed between 0 V and -0.75 V vs. the reference in Na_3AlF_6 - Al_2O_3 -KF at KF concentrations between 1% to 3% wt. %. However, the plateau expanded to -1.1 V vs. the reference when the KF concentration exceeded 3% (wt. %). The current density of this plateau was nearly zero with a slow increase, which suggests the formation of an aluminum-tungsten compound during this potential range controlled by mass transport. A subsequent increase of the cathodic current density was also observed, which may be attributed to the deposition of aluminum metal, although the deposition potential varied with KF concentration. Consequently, it can be deduced that the deposition potential of aluminum was slightly negative when the KF concentration was more than 3% (wt. %). The current density was largest during the deposition of aluminum in the melt at 3% KF, which suggests that the deposition rate of metal aluminum is faster. During this scanning range, the current density increased continuously, suggesting that the deposition of aluminum was primarily controlled by electron transfer. The large size of the cathodic current was caused by the deposition of aluminum on the surface of the electrode. Furthermore, the deposition potential of aluminum shifts more negative as the KF concentration increased, which confirms that a higher KF concentration induces a higher cathodic overpotential. According to the aforementioned analysis, it can be concluded that the reaction of aluminum(III) is controlled by mass transport and electron transfer in Na_3AlF_6 - Al_2O_3 melts.

Recurrent Potential Double Pulses

Potentiostatic double pulse measurements was used to measure the cathodic current efficiency for aluminum metal deposition. The anodic oxidation of aluminum and the aluminum-tungsten compound were performed between -0.6 V to -0.8 V vs. the reference. Other conditions

Fig. 1 Potentiodynamic cathodic polarization curves of $\text{Na}_3\text{AlF}_6\text{-Al}_2\text{O}_3$ at the tungsten electrode as a function of KF concentration

included a cryolite ratio of 2.5, a working electrode area of 1 cm^2 , a temperature of 1253 K , an Al_2O_3 concentration of 3% (wt %), a cathodic deposition time, t_c , of 5 s , and an anodic oxidation time, t_a , of 20 s . The lower value at the tungsten electrode was selected to prevent oxidation of the substrate. Fig. 2 shows the results corresponding to the deposition and reoxidation of aluminum at a tungsten electrode in a cryolite-luminum oxide melt. The cathodic current density was observed to rise sharply to between -0.2 mA/cm^2 and -0.45 mA/cm^2 by the reduction of aluminum(III) to aluminum. Upon reversal of the potential, a reverse transition is observed corresponding to reoxidation at the interface between the deposited metal and the substrate. However, the current plateau is more

pronounced when the KF concentration was less than 3% (wt. %), probably due to more uniform current distribution or a lower free convection rate. Furthermore, by integration, the cathodic and anodic current densities, Q_c and Q_a , respectively, were calculated. The anodic current density dropped essentially to zero because all deposited aluminum had reacted. It can be deduced that the ratio Q_c/Q_a decreased as KF concentration increased, which suggests that the rate of aluminum loss is higher at larger KF concentrations due to more convection.^[16] found that when the KF concentration was above 1% (wt. %), the current efficiency may be reduced considerably from Faraday's law after weighing the amount of deposited aluminum. Our results are in agreement with.^[16]

Fig. 2 Recurrent potential double pulses of $\text{Na}_3\text{AlF}_6\text{-Al}_2\text{O}_3\text{-KF}$ at the tungsten electrode

Potentiostatic Electrolysis

Potentiostatic cathodic polarization curves were measured (Fig. 3) by electrolysis for two hours in $\text{Na}_3\text{AlF}_6\text{-Al}_2\text{O}_3$ as a function of KF concentration at the tungsten electrode using the deposition potential of aluminum. The current density was recorded as the electrolysis time increased. The results showed that the current density was almost independent of the polarization time. An abrupt decrease while the initial scanning proceeds was seen in all curves, and the current density slowly reached a constant value. This feature is attributed to a deficiency of the electroactive constituent in the diffusion layer and that sodium vapor (boiling point: 1156 K) was not released with the deposited aluminum. In other words, the deposition potential of sodium metal shifted to a more negative potential following the addition of KF into the melt.

Chronopotentiometry

Chronopotentiometry curves were performed at various current densities at the tungsten electrode in $\text{Na}_3\text{AlF}_6\text{-Al}_2\text{O}_3\text{-KF}$ at 1253K (Fig. 4) to demonstrate the relationship between polarization time and electrode potential using 3% KF.

The results show plateaus at different potentials when the current density was between 150 mA/cm² and 400 mA/cm², corresponding to the potentials for the formation of the aluminum-tungsten compound and the reduction of aluminum(III) to aluminum. The potential ranges of the formation of aluminum-tungsten compound and the electrochemical deposition of metal aluminum were the same as those observed in the potentiodynamic cathodic polarization curves. From Fig. 4, when

the current density was higher than 350 mA/cm² and KF concentrations exceeded 3% (wt. %), only one potential plateau (τ_2) associated with the deposition of aluminum is observed. However, when the potential reached the value of the deposition potential of aluminum corresponding to one plateau (τ_2), and when KF concentration was below 3% (wt. %), the current density was less than 350 mA/cm². Consequently, it can be deduced that the deposition potential of aluminum was more negative as the KF concentration increased.

Open-Circuit Chronopotentiometry

Several open-circuit chronopotentiometry measurements were performed at the tungsten electrode. Figure 5 shows the open-circuit potential on the working electrode recorded after 600 s of aluminum electrolysis at a cathode potential of -1.1 V vs. the reference, demonstrating spontaneous dissolution at the surface of the cathode. This dissolution induces a decrease of the open circuit potential, which was stabilized at values characteristic of the products formed during cathodic polarization. Some plateaus were observed at the potentials corresponding to the dissolution of deposited aluminum and the aluminum-tungsten compounds. The duration of the plateaus corresponded to the dissolution time of the products. The first plateau, τ_1 , was related to the reoxidation of aluminum and its duration time was longer than the others when the KF concentration was 3% (wt. %), which suggests that the aluminum layer was thicker than at other concentrations. The second plateau, τ_2 , was associated with the dissolution of aluminum-tungsten compound. The third plateau at nearly -0 V vs. the reference was present because the tungsten electrode surface had no reduced species. The dissolution of the reduced products at the tungsten cathode under

Fig. 3 Electrolysis curves for two hours at the tungsten electrode in $\text{Na}_3\text{AlF}_6\text{-Al}_2\text{O}_3$ as a function of KF concentration

Fig. 4 Chronopotentiograms of $\text{Na}_3\text{AlF}_6\text{-Al}_2\text{O}_3\text{-KF}$ at the tungsten electrode as a function of applied current density

Fig. 5 Open-circuit potential transient curves after application of a potential of $E_c = -1.1$ V versus the reference by electrolysis for 600 s at the tungsten electrode in $\text{Na}_3\text{AlF}_6\text{-Al}_2\text{O}_3$ as a function of KF concentration

different potentials in open circuit measurement corresponds to the reactions in Fig. 1. It can be deduced that the thickness of metal aluminum and aluminum-tungsten compound stripped into the electrolyte increased up to a specific KF concentration and then decreased.

Scanning Electron Micrographs of Tungsten Working Electrodes

After two hours of aluminum electrolysis, the tungsten working electrodes were ground and polished for SEM

and the results are shown in Fig. 6. The tungsten electrodes can be divided into three layers. The first layer was the tungsten substrate, the second layer was an aluminum-tungsten compound, and the third was aluminum metal. The thickness of aluminum was dependent upon the KF concentration. When the KF concentration was more than 3% (wt. %), the aluminum layer was absent, which suggests that aluminum is easier to dissolved into the electrolyte. It is concluded that the concentration of aluminum was lower as KF concentration increases.

Fig. 6 Scanning electron micrographs of the cross-section of a tungsten cathode at 1253K after two hours of aluminum electrolysis in $\text{Na}_3\text{AlF}_6\text{-Al}_2\text{O}_3$: (A) KF 0%, (B) KF 1%, (C) KF 3%, (D) KF 5%, and (E) KF 7%

CONCLUSIONS

The electrochemical deposition of aluminum was studied in $\text{Na}_3\text{AlF}_6\text{-Al}_2\text{O}_3$ melts as a function of KF concentration by potentiodynamic polarization, recurrent potential double pulses, chronopotentiometry, open-circuit chronopotentiometry, and potentiostatic electrolysis. The results showed that the formation of an aluminum-tungsten intermetallic compound is predominantly controlled by mass transport and the deposition process of aluminum is primarily controlled by electron transfer. A more uniform current distribution or a lower free convection rate was deduced when KF concentrations were less than 3% (wt. %), and the loss rate of aluminum was higher at higher KF concentrations using the analysis of recurrent potential double pulses. The aluminum deposition potential shifted to more negative values as the KF concentration increased, inducing a higher cathodic overpotential. Based on open-circuit

potential measurements, as the KF concentration increased, the rate of conversion of aluminum(III) ions to aluminum metal and the decomposition of the cathode increased and then decreased. Furthermore, as the potassium fluoride concentration was more than 3% (wt. %) from the SEM images, the aluminum layer was absent, suggesting that aluminum metal is easily dissolved and the electrochemical decomposition of the cathode is more favorable.

Electrodeposition of Aluminum in Ionic Liquids

Qian Wang, Suojiang Zhang, Xingmei Lu, and Xiangping Zhang

Beijing Key Laboratory of Ionic Liquids Clean Process, CAS Key Laboratory of Green Process and Engineering, State Key Laboratory of Multiphase Complex Systems, Institute of Process Engineering, Chinese Academy of Sciences, Beijing, 100190, China

Abstract

Compared with the industrial Siemens-Galvano-Aluminum (SIGAL) process, electrodeposition of aluminum (Al) in ionic liquids (ILs) has gained more and more attention due to the excellent characteristics of ILs, such as almost non-volatile, wider electrochemical window, higher conductivity, and so on. Therefore, in this article we give a detailed report on the development of this field. In order to enhance the potential of ILs used as electrolytes for Al electrodeposition, this article also reviews the background and historical development of electrodeposition of Al in ILs. Through summarizing, we find that the chloroaluminate ILs with imidazolium as the cations are still the most prospective electrolytes for large-scale application, and moisture sensitivity is the biggest obstacle restricting its development. Therefore, researchers have been looking for stronger water resistant ILs, but the water insensitive ILs are hard to combine with low viscosity and high electrochemical conductivity, leading to little research work done for the industrial application of electrodeposition of Al in ILs. In addition, the existing problems in basic research and application of electrodeposition of Al in ILs are summarized.

Keywords: Al coatings; Electrodeposition; Electrolyte; Ionic liquids; Species.

INTRODUCTION

Researchers have been studying the preparation of metal coatings using the electrodeposition technique, mainly because it can produce coatings with certain thickness and does not affect the property of the substrates.^[1] However, Al has stronger reducibility than hydrogen, and its coatings cannot be electrodeposited from aqueous solution. Therefore, some nonaqueous electrolytes have been tried for obtaining Al coatings. There are mainly two kinds of electrolytes used, one is organic system, and the other is molten salt. Among these, Siemens-Galvano-Aluminium (SIGAL) is the only process used in industry, developed by Siemens laboratory using the electrolyte of alkylaluminum compounds dissolved in toluene.^[2] High-quality Al coatings have been obtained by the process, but the electrolyte is combustible and explosive, so it is still not the ideal choice.

The advent of ionic liquids (ILs) offers a chance for Al deposition because ILs have a series of suitable features for deposition such as wide electrochemical window, almost non-volatile, high conductivity, and so on.^[3,4] Compact and smooth Al coatings have been successfully deposited in many different types of ILs,^[5] in which chloroaluminate ILs are the preferred electrolytes due to their high conductivity, excellent chemical and thermal stability, and especially

their adjustable Lewis acid alkaline property by changing the ratio of AlCl_3 to the compounds providing cations.^[6,7] In our recent review, we have summarized the Al electrodeposition in chloroaluminate ILs from the point of view of influences of cations, additives, and deposition parameters. Furthermore, we compare the similarities and differences of electrodeposition in ILs with that in aqueous solutions.^[5] In this article, we review the electrodeposition of Al in ILs according to the type of the electro-active species, especially we focus on the system with cations as electro-active species. For the system with anions as electro-active species, we divide them into two categories, chloroaluminum ILs and nonchloroaluminum ILs, and review them according to the different types of cations. Through carding the processes of Al electrodeposition in ILs, we will sum up the performance of electrolytes of ILs and the development trends of the area and obtain the developing direction finally.

PRINCIPLE OF ELECTRODEPOSITION OF Al IN ILs

The most used Al sources for the electrolyte of electrodeposition is AlCl_3 , so the systems using other Al sources are not discussed here. When AlCl_3 dissolves in ILs, there will be two cases as shown in Fig. 1. In case I, the ILs

Fig. 1 Schematic dissolution of AlCl_3 in ILs with non-functionalized cations (I) and functionalized cations (II)^[7]

have non-functionalized cations, the anions of the ILs become ligands of AlCl_3 , in which the electro-active species will be the anions. In most cases, the ILs in case I are organic chloride (RCl), and the complex ILs form chloroaluminate ILs according to Eq. 1, and the electro-active species is Al_2Cl_7^- .^[7] In case II, the ILs have functionalized cations, the cations will complex with AlCl_3 , forming Al-containing cations, which are just the electro-active species. A typical example is the system formed by mixing amide with AlCl_3 as shown in Eq. 2. These form ILs through the asymmetric cleavage of AlCl_3 to AlCl_2^+ and AlCl_4^- .^[8] When Al_2Cl_7^- is the electro-active species, the Al coatings will be deposited on the substrate by taking place the following reaction shown in Eq. 3. While the electro-active species are Al-containing cations, the specific reaction is uncertain and Al coatings can really be obtained from them.^[9,10]

ELECTRODEPOSITION OF Al IN ILs WITH Al-CONTAINING CATIONS AS ELECTRO-ACTIVE SPECIES

Due to the hygroscopic nature of chloroaluminate ILs, researchers have been developing systems with superior performance, but it is reported that chloroaluminate ILs have better electrochemical performance than other ILs except that they are sensitive to water.^[7] However, the electro-active species in the chloroaluminate ILs is the abundant anions, Al_2Cl_7^- , and it is unfavorable for Al_2Cl_7^- to be reduced on the cathode, because like charges are repellent. If the electro-active species in ILs are cations, the current efficiency of the electrodeposition process will be improved based on the principle that unlike charges attract each other. In 2011, Abbott and coworkers reported the first ILs with Al-containing cations formed by mixing of simple amides, such as acetamide and urea, with AlCl_3 as shown in Eq. 2, in which $[\text{AlCl}_2 \cdot n\text{Amide}]^+$ was the electro-active species.^[8] In Fig. 2, the cyclic voltammograms of the electrolytes of AlCl_3 with acetamide (1) (50/50 mol%) and urea (2) (50/50 mol%) at room temperature were shown, and the typical Al reduction peak appeared, demonstrating Al coatings could be obtained from both of them. It was indeed that gray Al was electrodeposited on the copper substrate by applying a constant current of 2 mA cm^{-2} at 25°C as shown in Fig. 2 (inset). Then this group tried to use the IL mixed with AlCl_3 and urea to electrodeposit Al coatings under ambient conditions.^[11] The research idea is based on isolating the moisture sensitive IL from the atmosphere by using a protective

Fig. 2 Cyclic voltammogram of the electrolytes of aluminum trichloride with acetamide (1) (50/50 mol%) and urea (2) (50/50 mol%) at room temperature (Inset: Al coating obtained from bulk deposition)^[8]

hydrocarbon layer, allowing Al deposition to be carried out in an environment with ambient moisture and no need for a glove box. This idea came true, and thick adherent pure Al films were deposited on a range of substrates. Soon, this method of protecting the ILs from external intrusions was applied to the most used chloroaluminate IL ([Emim] Cl/AlCl₃), and successful electrodeposition of Al also had been achieved.^[12] Gao et al. also studied the electrodeposition of Al from the AlCl₃/acetamide IL and found that it was a potential electrolyte for Al electrodeposition at room temperature.^[13,14]

The following IL with an Al-containing cation was developed by Dai et al. The IL was obtained by mixing AlCl₃ with a “neutral” ligand, dipropyl sulfide (DPS), which was based on the group VI element of S, and the Al-containing cation was [AlCl₂·(DPS)₂]⁺.^[15] It could be seen from Fig. 3A that the IL was highly fluidic, and it was reported that the equivalent concentration of AlCl₃ in the IL was as high as 2.3 M, and its ambient ionic conductivity was 1.25×10^{-4} S cm⁻¹. The IR spectra in Fig. 3B confirmed that a new IL was generated from the complexation of AlCl₃ and DPS via the Al–S coordination interaction, and the new IL was successfully used for Al electrodeposition (Fig. 3C and D).

Recently, Dai et al. synthesized an IL by mixing AlCl₃ with another “neutral” ligand, 4-propylpyridine, in which the Al-containing cation was [AlCl₂·(4-Pr-Py)₂]⁺.^[16] The cyclic voltammogram of AlCl₃:4-Pr-Py (56.5/43.5 mol%) had a high peak of Al electrodeposition. A uniform Al layer was obtained in the IL, and its thickness could reach 3.9 μm after plating for only 1 h at 50°C.

ELECTRODEPOSITION OF Al IN ILs WITH ANIONS AS ELECTRO-ACTIVE SPECIES

Chloroaluminate ILs

As mentioned earlier, the widely used ILs for Al electrodeposition are the chloroaluminate ILs. According to the type of cations shown in Fig. 4, chloroaluminate ILs can be divided into five categories. We will summarize each category, respectively, in the following subsections.

Imidazolium System

The most used chloroaluminate ILs are the ones with alkylimidazolium cations due to their wider electrochemical window, lower viscosity, and higher conductivity, in which 1-ethyl-3-methylimidazoliumchloride/AlCl₃ ([Emim]Cl/AlCl₃) and 1-butyl-3-methylimidazoliumchloride/AlCl₃ ([Bmim]Cl/AlCl₃) are the preferred systems. Therefore, the following content will focus on the application of the two ILs for Al electrodeposition and review them in chronological order.

1980s. In 1982, Wilkes et al.^[17] discovered the [Emim] Cl/AlCl₃ IL with better electrochemical and physical properties than the early 1-alkylpyridinium chloride/AlCl₃ systems. Its Lewis acidity was determined by chloride activity and the CV data. Electrodeposition of Al in it was not reported, but the IL had been widely used to Al electrodeposition since then due to its superior properties.

In 1988, Lai et al.^[18] investigated the mechanism of the deposition of Al and dissolution reactions in [Emim]

Fig. 3 (A) Digital photo of DPS/AlCl₃ (48.8/51.2 mol%) IL. (B) FT-IR spectrum of DPS and DPS/AlCl₃ (50/50 mol%). Digital image and scanning electron micrograph (C) and energy-dispersive X-ray spectroscopy analysis (D) of electrodeposited Al on copper substrates^[15]

Fig. 4 Different types of cations of chloroaluminate ILs

Cl/AlCl₃. They reported that the Al deposition at glassy carbon, platinum (Pt), and tungsten (W) electrodes was preceded by a nucleation step and was kinetically complicated, and the Al deposition reaction was a quasi-reversible process.

1990s. In 1997, Zhao et al.^[19] reviewed the Al deposition in ILs, in which all the mentioned chloroaluminate ILs with alkylimidazolium cations was [Emim]Cl/AlCl₃, because [Emim]Cl/AlCl₃ had the best electrochemical properties by then. There were three important points in the mini-review on Al deposition in [Emim]Cl/AlCl₃: (1) The rate of deposition and stripping of Al in it was up to 25 A dm⁻², and the deposited Al was cycled with a high efficiency of 99%. (2) There was under potential deposition (UPD) of Al on W electrode. (3) The Al coatings obtained in [Emim]Cl/AlCl₃ (33.3/66.7 mol%) was dense, smooth, and corrosion resistant.

In the same year, the group of Charles L. Hussey in the United State reported that the addition of benzene as a “cosolvent” to the IL of [Emim]Cl/AlCl₃ could improve the quality of Al deposits greatly.^[20] All the obtained Al deposits exhibited a preferred (220) crystallographic orientation and the relative intensity of the (220) reflection increased as the concentration of benzene was increased.

2000s. In the 21st century, researchers do lots of work in the area of Al electrodeposition in ILs, in which the groups of Frank Endres in Germany and Andrew P. Abbott in the United Kingdom are the most famous, and they do many excellent work using [Emim]Cl/AlCl₃ and [Bmim]Cl/AlCl₃. Some of their work and part work of other representative groups are listed later.

Frank Endres’s Group In 2003, Endres’s group reported nanocrystalline Al was electrodeposited on glass carbon in [Emim]Cl/AlCl₃ with nicotinic acid as an organic additive, and the grain size of the obtained Al coating was 12 ± 1 nm. Later, they found that nanocrystalline Al could be directly obtained from air

and water stable ILs, and the details were discussed later.^[21] Then a new chloroaluminate IL with a cation of 1-(2-methoxyethyl)-3-methylimidazolium ([MoeMim]⁺) was synthesized based on the interest whether the structure of cations influenced the process of Al electrodeposition.^[22] The result showed that slight variations of the structure/composition of IL caused by the structure change of cations could alter the reaction pathway, resulting in significant effect on the deposits. As shown in Fig. 5, nanocrystalline Al was obtained in the IL with a methoxy group into the side chain of the imidazolium cation. Recently (in 2012), a more practical system using the mixture of [Emim]Cl/AlCl₃ and another chloroaluminate IL with a pyrrolidinium cation was used to deposit nanocrystalline Al, and they speculated that the presence of imidazolium cations altered the electrode/electrolyte interface, causing nanocrystalline Al obtained.^[23]

In addition, the group had made different nanowire architectures, such as free-standing nanowires, vertically

Fig. 5 (A) SEM micrograph of electrodeposited Al on gold formed after potentiostatic polarization for 1 h in [MoeMim]Cl/AlCl₃ (40/60 mol%) at a potential of -0.35 V at 100°C. (B) XRD patterns of electrodeposited Al layers obtained at 20°C and 100°C^[22]

aligned tree-shaped arrays, and bunched nanowire films, through a template-assisted electrodeposition technique, which had the potential applications in Li-ion micro-batteries.^[24] Also, the group explored the practical application of Al deposits in ILs. Here was an example. In 2006, Endres's group showed that mild steel could be coated by Al coating at room temperature in [Emim]Cl/AlCl₃ (40/60 mol%) IL.^[25] They found that the pretreatment of the substrates, in situ electrochemical etching of the substrate by anodic polarization, played a key role in the coating adhesion. The Al coating made on a conventionally pretreated mild steel substrate was of high quality, but it did not exhibit good adherence to the substrate, and this was attributed to the dissolution of the pre-formed iron oxide layer and the subsequent redeposition of iron or Fe–Al alloy prior to the bulk deposition of Al. In this way, not only steel sheets but also complex shapes like screws could be coated with well-adherent Al as shown in Fig. 6.

Andrew P. Abbott's Group In 2006, Abbott's group reviewed the electrodeposition of metal in ILs and pointed out that the main application of ILs was to use them for Al deposition because Al could not be electrodeposited in aqueous solution.^[4] Later (in 2010), the group investigated the effect of a diluent (toluene) and electrolyte (LiCl) on the morphology of Al deposited in the [Bmim]Cl/AlCl₃ IL, and they found that toluene could be used as a brightener for this system because the addition of toluene caused a change in speciation and a decrease in UPD of Al on Cu, which in turn changed the morphology of the Al deposit, but the addition of LiCl had the opposite effect.^[26] In the same year, the group succeeded in scaling up an Al plating process to a 20-L scale by using [Emim]Cl/AlCl₃ IL under a nitrogen atmosphere in the plant, which was the only work done for industrialization of this process.^[1]

Until 2009, [Emim]Cl/AlCl₃ was the widely used alkyylimidazolium chloroaluminate IL due to its good electrochemical property, but the raw material of [Emim]

Cl was difficult to synthesize. Therefore, [Bmim]Cl was used instead of [Emim]Cl. Since then, [Bmim]Cl/AlCl₃ IL is the most preferred because it owns good electrochemical property and low price. Benzene and nicotinic acid were the earliest and most used additives in the electrolyte of [Emim]Cl/AlCl₃. Since [Bmim]Cl/AlCl₃ was synthesized, Abbott first tried toluene in the system, and bright Al coating was deposited on the Cu substrate. Later, Barchi et al.^[27] obtained Al deposits on the car wheel bolt in [Bmim]Cl/AlCl₃ IL using 1,10-phenantroline as an additive for anticorrosive and decorative purposes. The obtained Al coatings had nearly the same corrosion resistance as the Ni–Cr and were bright and almost good looking as the Ni–Cr.

I-Wen Sun's Group Another group that must be mentioned was the I-Wen Sun in Taiwan. In 2007, this group first electrodeposited Al onto a magnesium (Mg) alloy substrate in [Emim]Cl/AlCl₃ IL as a protective layer to improve the anticorrosion ability of the Mg alloy.^[28] The deposited Al layer showed an excellent corrosion resistance in 3.5 wt% NaCl solution, evaluated by electrochemical impedance spectroscopy (EIS) and potentiodynamic polarization measurements (Fig. 7). The EIS data in Fig. 7A showed the polarization resistance (R_p) of the –0.2 V Al-coated sample was ten times greater than that of the bare Mg alloy, indicating that the Al coating led to an improvement in corrosion resistance. The passive current densities of the samples shown in Fig. 7B revealed that the dissolution rates of the –0.2 V Al-coated and –0.4 V Al-coated samples were highly suppressed as compared to that of the bare Mg alloy. In the next two years, they published two full papers introducing the work in detail.^[6,29] In 2012, Tang et al. in Hokkaido University improved the adhesive strength of Al coatings electrodeposited on the Mg alloy substrate in [Emim]Cl/AlCl₃ IL by the development of a zincate pretreatment and an optimized current pulse electrodeposition method.^[30] The pulse electrodeposition is an effective method to obtain adhesive, dense, and smooth Al deposits, which can be attributed to the good supply of Al ions to the electrode surface and the lower overpotential for deposition reaction by slight anodic dissolution, removing active sites for preferential Al deposition.^[31]

In recent years, researchers have started to improve the morphologies of Al deposits obtained in alkyylimidazolium chloroaluminate ILs based on the awareness that the alkyylimidazolium chloroaluminate ILs have better properties to electrodeposition of Al, but the deposited Al is microcrystalline and is dendritic sometimes. Some methods have been tried, and they are two main categories. One is changing the pattern of electrodeposition, and the other is addition of additives. So far, the former way is rarely used, and the latter is widely used due to its convenience. They mainly used additives can be divided into diluents and inorganic/organic compounds.

Fig. 6 An optical photo of deposits manufactured from the employed IL with uneven surface and screw geometry. The Al (bright) is at the upper part of the sheets, and at the lower part of the screw^[25]

Fig. 7 Nyquist plot (A) and Potentiodynamic polarization curves (B) of the various samples. Curve a, b and c present the bare Mg alloy, 0.2 V Al-deposited samples, and 0.4 V Al-deposited samples, respectively. The measurement was performed in 3.5 wt% NaCl solution^[28]

Al Electrodeposition in China Li's group in China tried both the earlier two methods. In 2009, they prepared LaCl_3 -saturated $[\text{Emim}]\text{Cl}/\text{AlCl}_3$ electrolyte.^[32] The cyclic voltammetry curve showed that Al deposition potential shifted negative with additive of LaCl_3 . What's more, very smooth surface was obtained at the current density of 12 mA cm^{-2} after LaCl_3 was added. In 2011, they also obtained Al deposits from $[\text{Emim}]\text{Cl}/\text{AlCl}_3$ IL with or without the addition of LaCl_3 by both direct- and pulse-current plating methods.^[33] They found that deposits prepared by pulse-current plating gave a brighter and flatter surface at appropriate pulse current parameters, and temperature and pulse-current frequency were shown to significantly affect deposit morphology. Raising temperature was bad for obtaining Al coating with smooth surface and well-adhered Al coatings.

In fact, $[\text{Bmim}]\text{Cl}/\text{AlCl}_3$ was the most used electrolyte for Al electrodeposition in our group. The first work was done by Yue and coworkers.^[34,35] They made a systemic research on electroplating of Al using $[\text{Bmim}]\text{Cl}/\text{AlCl}_3$ IL as an electrolyte and summarized the effect of current density, temperature, plating solution molar ratio, stirring time, and plating time on the properties of the Al deposits. Dense, bright, and adherent Al deposits were obtained over a wide range of temperature (298–348 K), current densities ($8\text{--}44 \text{ mA cm}^{-2}$), and molar ratio (38.5/61.5–33.3/66.7 mol%). Results from the analysis of crystal structure showed that all of the electrodeposits exhibit a preferred (200) crystallographic orientation. They discovered that temperature had a significant influence on the crystallographic orientation, and there did not appear to be an apparent impact of current density on it. The next section was done by Zheng and coworkers.^[36] They tested the

viscosity, density, and electrical conductivity of $[\text{Bmim}]\text{Cl}/\text{AlCl}_3$ IL systematically and compared them with that of $[\text{H}_1\text{mim}]\text{Cl}/\text{AlCl}_3$ IL. The latest work was done by Wang and coworkers.^[37–39] They investigated the effect of some pyridine derivatives (nicotinic acid, methyl nicotinate, nicotinamide, and 3-methyl pyridine) on the morphologies of Al coatings obtained from $[\text{Bmim}]\text{Cl}/\text{AlCl}_3$ IL.^[38] It has been summarized from series of research results that pyridine derivatives with electron-withdrawing groups (nicotinic acid,^[37] methyl nicotinate, and nicotinamide^[38]) have stronger adsorption ability on the cathode, and they are effective brighteners. By contrast, the pyridine derivative with an electron-donating group (3-methylpyridine) has a weak adsorption ability and cannot be used as a brightener. Furthermore, the research results have proved that the brighteners refine the grain size, orient the Al (200) plane, and level the deposits; thus, Al coatings with highly uniform and smooth surface are obtained.^[39]

Pyridinium System

The cation of the first reported chloroaluminate ILs is alkylpyridinium. In 1951, a room temperature molten salt system comprising 67 mol% AlCl_3 and 33 mol% ethylpyridinium bromide (EPB) was reported by Hurley and Wier, and that was EPB/ AlCl_3 IL, the earliest chloroaluminate IL.^[40] Unfortunately, EPB/ AlCl_3 IL suffered from easily decomposing in light, variable melting point which was easily changed by the ratio of components, and the narrow electrochemical window.

In 1979, Robinson and Osteryoung^[41] had developed an IL of *n*-butylpyridinium chloride (BPC)/ AlCl_3 , with a wide composition range from 62.5/37.5 to 31.3/68.7 mol%.

Soon afterwards, it was used for Al electrodeposition. However, the BPC/ AlCl_3 has a narrow electrochemical window due to the easy reduction of the pyridinium cation, and Al has a bad stability in it. Therefore, BPC/ AlCl_3 IL cannot meet the requirements as the electrochemical electrolyte.

After 1982, the [Emim]Cl/ AlCl_3 IL was synthesized, and researchers began to use it because of its better electrochemical properties. Therefore, little work was done by using the chloroaluminate ILs with alkylpyridinium cations. Here, just two examples were mentioned. In 1994, Yang et al.^[42] investigated that electrodeposition of Al by DC constant current and pulse current methods in BPC/ AlCl_3 IL. They found Al could only be deposited when the IL was acidic. The influence of electrodeposition conditions (electrodeposition time, the current form, the electrolyte composition, and the current density) on the property of the deposit layer was investigated, and pulse current was good for obtaining Al coatings with smaller particle size and better adhesiveness. In 1999,^[43] Ali et al. had carried out electrodeposition of Al by controlled-current and controlled-potential methods from acidic BPC/ AlCl_3 IL at room temperature. The deposition reaction mechanisms of

Al in the bath were revealed by electrochemical analysis, suggesting that the rate-determining step was a chemical reaction involving the release of the complexing agents via three consecutive single electron transfer steps. It was also found that upon increasing the current density, smaller particle size and better adhesiveness of the electrodeposited Al layers had been obtained, and the cathodic current efficiency for the deposition of Al in acidic BPC/ AlCl_3 IL was about 99.8%.

Pyrrolidinium System

There are few studies on Al electrodeposition in chloroaluminate ILs with alkylpyrrolidinium as the cations. One impressive work was done by Endres's group that had been referenced earlier. Nanocrystalline Al was obtained from the mixture of 1-butyl-1-methylpyrrolidinium chloride ($[\text{Py}_{1,4}]\text{Cl}$)/ AlCl_3 and [Emim]Cl/ AlCl_3 .^[23] SEM images of the deposits obtained from various compositions of the mixture are shown in Fig. 8A–F. They speculated that the strong adsorption of $[\text{Py}_{1,4}]^+$ to the surface of the growing nuclei hinders their further growth, leading to very fine particles with sizes in the nanometer regime.

Fig. 8 (A and B) SEM micrographs of Al deposits obtained from electrolysis of 90:10 vol% and 80:20 vol% of (40/60 mol%) $[\text{Py}_{1,4}]\text{Cl}/\text{AlCl}_3$; [Emim]Cl/ AlCl_3 on gold at -0.3 V for 1 h at 100°C . (C and D) SEM images of Al deposits obtained from 70:30 vol% and 60:40 vol% of (40/60 mol%) $[\text{Py}_{1,4}]\text{Cl}/\text{AlCl}_3$; [Emim]Cl/ AlCl_3 on gold at -0.3 V for 1 h at 100°C . (E and F) SEM images of electrodeposited Al on gold after constant potential electrolysis of 50:50 vol% of (40/60 mol%) $[\text{Py}_{1,4}]\text{Cl}/\text{AlCl}_3$; [Emim]Cl/ AlCl_3 and pure [EMIm]Cl/ AlCl_3 (40/60 mol%) at an applied potential of -0.30 V for 1 h at 100°C ^[23]

Quaternary Ammonium System

Quaternary ammonium ILs have many good performances such as wide variety, ease of synthesis, and lower price, but their low conductivity limits their practical application.

TMPAC/ AlCl_3 . A typical and most used example of this kind of ILs was formed by mixing the trimethyl-phenyl-ammonium chloride (TMPAC) with AlCl_3 . It was found that the electrochemical stability of the TMPAC/ AlCl_3 IL was equal to that of $[\text{Emim}]\text{Cl}/\text{AlCl}_3$, and its electrical conductivity was comparable to that of BPC/AlCl_3 although it was lower than that of $[\text{Emim}]\text{Cl}/\text{AlCl}_3$.^[44] Therefore, TMPAC/ AlCl_3 IL was considered as a very suitable electrolyte for the electrochemical field, and it was studied from time to time.

In 1993, Papageorgiou et al.^[45] evaluated the small Gutmann donor number solvents of 1,2-dichlorobenzene, anisole, and diphenylether as cosolvents of the TMPAC/ AlCl_3 IL to explore the potential use of these mixed systems in batteries. They proved that Al deposition was faster on a pure Al electrode than on amalgamated Al when anisole was used as a cosolvent, but the solutions had very low conductivity. Diphenylether could be used together with 1,2-dichlorobenzene, but such solutions showed marked passivation in the cathodic region.

In 1997, Zhao et al.^[46] investigated the Al deposition processes on W in TMPAC/ AlCl_3 IL using cyclic voltammetry and chronoamperometry and found that the reduction of Al_2Cl_7^- ions was quasi-reversible, and the deposition of Al was instantaneous three-dimensional nucleation with hemispherical diffusion-controlled growth. It was observed that five monolayers of UPD of Al on W were formed. It was reported that the diffusion coefficient of Al_2Cl_7^- were $2.17 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$ from cyclic voltammetry and $2.45 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$ from chronoamperometry, and its Stokes-Einstein product was $2.6 \times 10^{-10} \text{ g cm s}^{-2} \text{ K}^{-1}$.

In 2006, Jiang et al.^[47] also studied the nucleation processes of Al electrodeposits on W in TMPAC/ AlCl_3 . In addition, they also used Al as the substrate and found that the deposition processes of Al on both W and Al substrates were controlled by an instantaneous nucleation with diffusion-controlled growth. As shown in Fig. 9, UPD of Al on W was also observed. Dense Al electrodeposits could be obtained on both W and Al substrates at various current densities ($50\text{--}200 \text{ mA cm}^{-2}$) and temperatures (60°C and 90°C), which was unlike that of their previous work in $[\text{Emim}]\text{Cl}/\text{AlCl}_3$ IL.

In 2011, Liu et al.^[48] reported that Al was electrodeposited with constant current on AZ31 Mg alloy in TMPAC/ AlCl_3 IL with benzene as a co-solvent. Al was used as the protective layer of Mg alloy, and their results showed thicker Al deposits were more effective protective coatings and the Al deposits with bulk grains hardly protected the AZ31 Mg substrate from corrosion owing to its porosity.

$\text{Et}_3\text{NHCl}/\text{AlCl}_3$. Triethylamine hydrochloride (Et_3NHCl)/ AlCl_3 is a kind of IL with low cost, low

Fig. 9 A series of cyclic voltammograms revealing UPD and stripping of Al on W electrodes in TMPAC/ AlCl_3 (33/67 mol%) IL at 60°C . Scan rates ($\nu \text{ s}^{-1}$): (a) 0.05; (b) 0.08; (c) 0.10; (d) 0.12; (e) 0.15; (f) 0.20; (g) 0.30; (h) 0.40; (i) 0.50; (j) 0.60. The inset graph shows the UPD deposition peak current (i_{pc}) as a function of the scan rate (ν)^[47]

melting point, and high conductivity.^[49] In 2008, Gao et al.^[50] successfully electrodeposited Al on Al electrodes from $\text{Et}_3\text{NHCl}/\text{AlCl}_3$ IL by the constant potential electrolysis. The electrical conductivities of the IL increased as the temperature increased. The obtained Al electrodeposits were dense, continuous, and well adherent, and the purity was above 96% (w). The current efficiency was 73% at -2.4 V (vs. Pt) for 20 min electrolysis at room temperature.

In 2013, Suneesh et al.^[51] carried out the electrodeposition of Al onto gold (Au) substrates from $\text{Et}_3\text{NHCl}/\text{AlCl}_3$ IL. The electrochemical behavior of the electrolyte and the mechanism of deposition were investigated through CV. Al of $70 \mu\text{m}$ in thickness was deposited from the electrolyte, and the Al deposit was smooth and uniform as seen in the SEM images. The average crystalline size of Al deposits was $30 \pm 5 \text{ nm}$ determined by XRD patterns.

In 2013, Su et al.^[52] successfully electrodeposited Al wires on W substrate from $\text{Et}_3\text{NHCl}/\text{AlCl}_3$ IL without using a template, and the Al wire could also be deposited on other substrates such as GC, Pt, and Al. It was proposed that the trimethylamine adhered strongly to some facets of Al causing the growth of Al prefers in one direction to form wires. The key point of the method was using a quiescent solution and low temperature, because convection and raising deposition temperature would destroy the structure of Al wire. Recently (in 2015),^[53] they found potential oscillation during the template-free galvanostatic deposition of Al in $\text{Et}_3\text{NHCl}/\text{AlCl}_3$ IL, and unique periodic (accordion-like) Al wires shown in Fig. 10 were obtained. It was postulated that the diffusion layer thickening and electrolyte resistance variation during the deposition caused the forming of the periodic Al wires.

Fig. 10 Galvanostatic electrodeposition of Al wires at 0.25 mA cm⁻²: (A) Potential recorded as a function of electrolysis time, and (B) SEM micrograph of the as-deposited Al wires. (C) Potential oscillations observed at current densities of 0.25 and 1.25 mA cm⁻², respectively, and (D) the period of the potential oscillation as a function of deposition charge determined at different current densities^[53]

BTMAC/ $AlCl_3$. The advantages of benzyltrimethyl ammonium chloride (BTMAC)/ $AlCl_3$ IL over the majority of those previously investigated are that it is more water stable, easier to synthesize and purify, and highly cost effective. Abbott et al.^[54] investigated Al deposition and stripping on Pt, Al, and Fe electrodes in the BTMAC/ $AlCl_3$ IL. Optimum deposition conditions were screened out by Hull cell and uniform, adherent, and crack-free Al deposits were obtained in the IL.

BTEAC/ $AlCl_3$. Recently, Ma et al.^[55] studied Al electrodeposition on copper substrates from Benzyltriethylammonium Chloride (BTEAC)/ $AlCl_3$ IL at ambient temperature. They also analyzed the diluents on the conductivity of the IL and the nucleation of this process. Under certain conditions, Al coatings with good surface and adhesion to the substrate were obtained.

Quaternary Phosphonium System

The ILs with quaternary phosphonium as cations are thermally stable over a wide range of temperatures and less volatility compared with the ones with quaternary ammonium

cations. However, the lower conductivity limited their application to some extent. In 2008, Vaughan et al.^[56] studied Al-electroplating at a constant potential over a range from 0.3 to 0.75 V at 100°C in trihexyl (tetradecyl) phosphonium chloride ($[P_{14,6,6,6}]Cl$)/ $AlCl_3$ (33.3/66.7 mol%). Unfortunately, only few Al was deposited due to the lower conductivity. Therefore, this system has been less studied in recent years.

Nonchloroaluminate ILs System

Nonchloroaluminate ILs used for Al electrodeposition are the water and air stable ones, in which only imidazolium and pyrrolidinium are used as the cations to our knowledge. The most used anions are bis-trifluoromethylsulfonyl (Tf_2N), trifluoromethylsulfonate (TFO), and dicyanoamide (DCA), and their structures are shown in Fig. 11.

Imidazolium System

As we know, most researches on Al electrodeposition in nonchloroaluminate ILs were done by the group

Fig. 11 The structure of anions used for Al electrodeposition in nonchloroaluminate ILs

of Endres Frank, and the anion they used was mainly Tf_2N . In 2006, they investigated Al electrodeposition in 1-ethyl-3-methylimidazolium bis-(trifluoromethylsulfonyl) amide ($[\text{Emim}]\text{Tf}_2\text{N}$) IL, and AlCl_3 was used as the Al source.^[57,58] Later, a comparison on Al electrodeposition in $[\text{Emim}]\text{Tf}_2\text{N}/\text{AlCl}_3$ and $[\text{Emim}]\text{Cl}/\text{AlCl}_3$ was made. It was found that nanocrystalline Al could be obtained by electrodeposition from both ILs at room temperature without additives. It was speculated that the decomposition of the imidazolium ions refined the crystal size to a certain extent, forming nanocrystalline Al.^[59] Meanwhile, in situ scanning tunneling microscopy (STM) and electrochemical quartz crystal microbalance (EQCM) were used to study the process of Al deposition on Au(111) and polycrystalline Au substrates in the electrolyte of 1-butyl-1-methyl-pyrrolidinium bis(trifluoromethylsulfonyl)amide ($[\text{Py}_{1,4}]\text{Tf}_2\text{N}/\text{AlCl}_3$ and 1-ethyl-3-methyl-imidazolium bis-(trifluoromethylsulfonyl)amide ($[\text{Emim}]\text{Tf}_2\text{N}/\text{AlCl}_3$).^[60] Al deposition and stripping on Au(111) in the upper phase of the biphasic mixture of $[\text{Emim}]\text{Tf}_2\text{N}$ with AlCl_3 at 25°C showed that the Al electrodeposition process was completely reversible, and the deposition was not fully reversible in $([\text{Py}_{1,4}]\text{Tf}_2\text{N})/\text{AlCl}_3$. Furthermore, the UPD of Al in $[\text{Py}_{1,4}]\text{Tf}_2\text{N}$ was not as clear as in $[\text{Emim}]\text{Tf}_2\text{N}$.

In addition, the group of Sun used the ILs of 1-ethyl-3-methylimidazolium dicyanamide ($[\text{Emim}]\text{DCA}$) and 1-butyl-3-methylimidazolium dicyanamide ($[\text{Bmim}]\text{DCA}$) to electrodeposition of metals such as Al, Mn, Ni, Zn, Sn, and Cu.^[61] It was found that DCA-based ILs exhibited lower viscosity and higher solubility of metal chlorides, and it was significant that they could be used to electrodeposit reactive metals such as Al and Mn.

Pyrrolidinium System

Due to the stability and wider electrochemical window, more nonchloroaluminate ILs with pyrrolidinium cations were synthesized to electrodeposit Al. Most of these works were reviewed in Table 1. From the publications summarized earlier, we found that when nonchloroaluminate ILs with pyrrolidinium cations were mixed with AlCl_3 , a bi-phase was formed and the upper one was used as the electrolyte of Al electrodeposition. As shown in Fig. 12, the obtained Al from the upper electrolyte was nanocrystalline in most cases, which was speculated that the pyrrolidinium cations might act as a grain refiner, leading to nanosized deposits.

Rocher et al. revealed the Al speciation in the 1-butyl-1-methylpyrrolidinium bis(trifluoromethylsulfonyl) amide ($[\text{C}_4\text{mpyr}]\text{Tf}_2\text{N}$) IL using ^{27}Al NMR spectra and Raman spectra shown in Fig. 13.^[66] The results indicated that either $[\text{AlCl}_3(\text{Tf}_2\text{N})]^-$ or $[\text{AlCl}_2(\text{Tf}_2\text{N})_2]^-$ was likely to be the electro-active species involved by using $\text{Al}(\text{Tf}_2\text{N})_3$ as a comparison.

Abedin et al.^[58,62] studied the Al electrodeposition in the IL of trihexy-tetradecyl-phosphoniumbis(trifluoromethylsulfonyl)imide ($[\text{P}_{14,6,6,6}]\text{Tf}_2\text{N}$). It was found that the AlCl_3 could be completely dissolved in $[\text{P}_{14,6,6,6}]\text{Tf}_2\text{N}$ and did not show biphasic behavior. A very thin Al film with mirror-like appearance was obtained in the IL. The SEM image showed that the layer contained nanocrystalline Al with an average size of about 20 nm (Fig. 14A). The EDAX revealed that the purity of the Al layer was high, and some oxygen in it might be due to the exposure to air (Fig. 14B).

Table 1 Summarization of Al electrodeposition in nonchloroaluminate ILs with pyrrolidinium cations

Used ILs		Substrates	Literatures
1-butyl-1-methylpyrrolidinium bis(trifluoromethylsulfonyl) imide	$([\text{BMP}]\text{Tf}_2\text{N})$	Gold/Glass carbon	[21,62,63]
1-butyl-1-methylpyrrolidinium bis(trifluoromethylsulfonyl)amide	$([\text{Py}_{1,4}]\text{Tf}_2\text{N})$	Mild steel	[64]
N-methyl-N-alkylpyrrolidinium dicyanamide	$([\text{BMP}]\text{DCA})$	Copper	[61]
1-butyl-1-methylpyrrolidinium trifluoromethylsulfonate	$([\text{Py}_{1,4}]\text{TFO})$	Gold	[65]
Trihexy-tetradecyl-phosphonium bis(trifluoromethylsulfonyl)imide	$([\text{P}_{14,6,6,6}]\text{Tf}_2\text{N})$	Gold	[62]

Fig. 12 SEM micrographs of electrodeposited Al on gold formed after potentiostatic polarization for 2 h in the upper phase of the mixture AlCl_3 /[BMP] Tf_2N : (A) at room temperature, $E = -1.7$ V; (B) at 100°C , $E = -0.45$ V. (C) EDAX profile for the area shown in the SEM micrograph (A)^[21]

CONCLUSION

Through the above summarization, it is not difficult to see that the electrodeposition process in ILs is more complex than that in aqueous solution due to the different hole-jumping mass transport method and the uncertain interfacial structure of the IL/electrified substrate, and most of the studies on Al electrodeposition in ILs are fundamental research. As for basic research, the following two questions need to be answered:

1. Make sure the nucleation process of the Al electrodeposition in ILs. So far, researchers thought that the electrodeposition of Al in chloroaluminum ILs was controlled by an instantaneous nucleation with diffusion-controlled growth, and little studies focus on the system of non-chloroaluminum ILs. Actually, the high concentration of electro-active species in chloroaluminum ILs makes it hard to confirm the system follows the mass transport method, and more professional research is needed. For the system of non-chloroaluminum ILs, the first thing to do is making clear their electro-active species, thus it is reasonable to discuss the nucleation mode.
2. It is an effective method to improve the properties of IL electrolytes and obtain Al coatings with excellent performances by using additives suitable for the electrolyte of ILs. For example, diluents can decrease the viscosity and increase the electrical conductivity of electrolyte. However, how the species change after additives were added is unknown, and detection methods (Raman and NMR) used are not sufficient. Therefore, the development of new and reliable methods for species detection is another key issue.

Little work of scale-up has been done for Al electrodeposition in ILs. For the efficient use of the process in industry, the following problems are to be resolved:

1. Quantifying the ability of adsorption of water and the stability of most ILs under practical plating conditions. We just know that ILs are water-sensitive, but how much water can change the property of ILs is uncertain. Furthermore, how to improve the current density of ILs can bear is an important problem, because industrial plating using constant current and high current density, but most of the research in ILs is limited to the constant potential and under relative low current density.
2. How to recycle the used and performance-decreased ILs electrolyte is another big project. The biggest problem limiting the practical application of ILs is its high prices. If the recycle of the used ILs becomes mature, the price of ILs must fall, thus the practical application of ILs will become closer to us.

The above are some of the ideas presented for the existing ILs systems; another important work needed to do is developing new ILs with high performances, low prices and especially strong water-resistant. If a perfect IL electrolyte is found, the industrial application of Al electrodeposition in ILs will be easier to be realized.

Fig. 13 (A) ^{27}Al NMR spectra of $\text{C}_4\text{mpyrTf}_2\text{N}/\text{AlCl}_3$ mixtures at various AlCl_3 mole fractions. The presence of two different Al coordination geometries (tetrahedral, T_d , and octahedral, O_h) are clearly visible. The two spectra at the top are the ^{27}Al NMR spectra of $[\text{C}_4\text{mpyr}]\text{Tf}_2\text{N}/\text{Al}(\text{Tf}_2\text{N})_3$ mixtures at different $\text{Al}(\text{Tf}_2\text{N})_3$ mole fractions. (B) Raman spectra in the 150–400 cm^{-1} region of pure $\text{Al}(\text{Tf}_2\text{N})_3$, $[\text{C}_4\text{mpyr}]\text{Tf}_2\text{N}/\text{Al}(\text{Tf}_2\text{N})_3$ at $x_{\text{Al}(\text{Tf}_2\text{N})_3} = 0.33$, $[\text{C}_4\text{mpyr}]\text{Tf}_2\text{N}/\text{AlCl}_3$ at $x_{\text{AlCl}_3} = 0.50$ (upper and lower phase), and $\text{C}_4\text{mpyrCl}/\text{AlCl}_3$ chloroaluminate mixtures at $x_{\text{AlCl}_3} = 0.25, 0.50$ and 0.6 ^[66]

Electron Backscatter Diffraction

David P. Field and Mukul Kumar

Abstract

Electron backscatter diffraction (EBSD) is a scanning electron microscope (SEM) based technique that is used to obtain local information on the crystallographic character of bulk crystalline and polycrystalline materials. Topics discussed in this article include: EBSD system overview, multiphase analysis, and application to aluminum integrated circuit interconnects, dislocation structure analysis, analysis of grain boundary networks, and application to friction stir welding of aluminum alloys.

Keywords: Dislocation structure; EBSD; Grain boundary networks; Multiphase analysis.

INTRODUCTION

Electron backscatter diffraction (EBSD) is one of various scanning electron microscope (SEM) based techniques used to obtain local information on the crystallographic character of bulk crystalline or polycrystalline material. Because of the high spatial resolution, acceptable angular resolution, ease of adaptation to virtually any electron beam instrument, and automated data collection and mapping capability developed over the past decade, EBSD has become an important characterization tool in metallurgical, materials, and geophysical laboratories throughout the world. The technique was originally discussed by Alam, Blackman and Pashley in 1954^[1] and later investigated by Venables and co-workers.^[2,3] The early literature dubbed the technique wide-angle Kikuchi diffraction and it has been referred to by several additional acronyms in the past decade. Those that are most notable, other than EBSD, include backscatter Kikuchi diffraction (BKD) and backscatter electron Kikuchi diffraction (BEKD). (Note: Acronyms of EBSP, BKP, and BEKP are also common in literature and these refer specifically to the image formed by the diffraction technique, i.e., electron backscatter diffraction *pattern*.) Appendix 1 contains references to significant papers that mark the development of EBSD and automated EBSD analysis.

Figure 1 shows a typical EBSD image obtained from an Al–0.5 wt.% Cu film used in the fabrication of interconnected lines of integrated circuits. The image was obtained using a commercially available CCD (charge-coupled device) camera in a field-emission source SEM with a beam energy of 20 keV and 1 nA of probe current. In the early days of EBSD development, images were often recorded on photographic film placed inside the chamber. (The reader is referred to an atlas, published in 1995,^[4] of such images obtained from several different materials including metals, ceramics, and semiconductors.)

A distinct technique that produces similar images to EBSD in the SEM is selected area electron channeling diffraction. The principle of electron channeling is to rock the incident beam over a selected area of the specimen so as to cause incidence at all angles within a solid cone of semi-apex angle in the range 5 to 10°. The image is formed on the backscattered electron detector by the diffracted electrons with contrast provided by the electron channeling effects of the given crystallite under investigation. Disadvantages of the technique relative to EBSD include relatively poor spatial resolution (>1 µm) and slow image formation (>1 sec). Further comparison of SEM-based diffraction techniques is found in Refs. [5] and [6].

To obtain EBSD patterns in a typical SEM having a vertically positioned column, the specimen is tilted at a high angle from horizontal (60 to 80° is typical). A scintillating screen is positioned near the specimen to detect the diffraction pattern as shown in Fig. 2. While the SEM is the instrument of choice, EBSD can be performed on virtually any instrument that provides a coherent beam of electrons. The required hardware consists of a scintillating screen (usually a phosphor coated glass), a low-light camera that can be focused on the phosphor screen, and the requisite mechanical interface that allows proper mounting of the screen and camera to the SEM chamber. Digital or analog interfacing to the SEM for control of the electron beam and specimen stage is also required for automated and unattended operation.

No intensive specimen preparation is required for patterns to be obtained and for thin films there are typically no requirements other than ensuring that the bare metal surface is exposed. Diffraction patterns are reliably obtained directly after deposition of the metal (without a passivation layer), or after CMP processing. For bulk specimens a final mechanical polish using 0.05 µm colloidal silica suspension is typically adequate. In rare instances, the final step must be chemical or electrochemical polishing to remove

Fig. 2 Geometry of the specimen, phosphor screen, and electron beam required for EBSD analysis

residual surface deformation caused by mechanical surface preparation techniques. With some specimens, particularly thin films with surfaces contaminated or covered by an oxide layer, it is convenient to use broad beam ion techniques in surface preparation.^[7,8]

Resolution of the technique is dependent upon the SEM type and atomic number of the metal film. Lateral spatial resolution down to 10 nm in a field-emission source SEM has been reported.^[9,10] This resolution is achievable because the Kikuchi bands in the diffraction patterns are generated from the elastically scattered electrons that are near the energy of the incident beam. Depending upon atomic number of the material being investigated and the accelerating potential of the electron beam, these electrons are scattered from approximately 10 nm or less below the surface.^[3,9]

Automated indexing of EBSD patterns was developed in the early part of the 1990s by two independent groups of researchers, one in the United States^[11–13] and the other in Denmark.^[14,15] The automated analysis and orientation mapping has been commercially available since 1994 and

is known by acronyms such as OIM (orientation imaging microscopy), ACOM (automated crystal orientation mapping), or simply crystal mapping. During mapping, individual crystallite lattice orientation, phase (crystal structure), and a measure of local lattice integrity are obtained from the backscatter diffraction patterns. These are stored along with x - y coordinates on the specimen surface and can be used to regenerate images of the specimen surface based upon the requirements of the investigation.

A complete description of the hardware required for EBSD along with a discussion of the mathematics and physics of the technique is published in detail elsewhere^[16,17] and will not be fully addressed in the present chapter. It suffices herein to briefly cover EBSD image formation and strategy for automated analysis and phase identification considerations. Applications to analysis of aluminum films, friction stir joining, and bulk deformation of aluminum alloys is also discussed. A final section detailing application of automated EBSD analysis and characterization of grain boundary networks is also briefly included. EBSD techniques have been successfully applied in investigations of Al deformation, recrystallization, grain growth, and various additional phenomena not specifically addressed herein. For further study on a specific area, the reader is referred to Section A. 10.2, which contains a selection of recent published research on the applications of EBSD to investigations involving Al and Al alloys.

EBSD SYSTEM OVERVIEW

Orientation imaging is enabled by rapid and automated analysis of electron backscatter diffraction patterns using sophisticated software algorithms. The quality of the image captured by the computer and the speed at which it is obtained controls the utility of the information acquired during an automated scan. Image quality and speed of obtaining the image can vary extensively from one system to the next. The hardware variables that influence the quality of the EBSD imaging scan are the topic of the following discussion.

The components of an EBSD imaging system are listed below:

- Electron source (typically an SEM).
- Mechanical interface/phosphor screen.
- Camera system.
- Software/indexing algorithms.

SEM/Electron Source Considerations

The electron source for backscatter diffraction is typically an SEM column, but it could be an electron beam from any source, inside a vacuum chamber. The major considerations for the SEM are: (a) beam integrity, (b) specimen stage utility, and (c) port configuration.

Electron Beam Integrity

The character of the electron beam and the quality of the imaging system determines the spatial resolution obtainable for a given material. The factors of primary concern are:

Accelerating Voltage: EBSPs have been observed at voltages as low as 2.5 kV^[18] but more typical working potentials are between 10 and 30 kV.

Probe Current: The amount of current required to form a viewable EBSD image on a phosphor screen depends upon the camera system and various additional factors. Typical camera systems consist of silicon intensified target (SIT) cameras, TV rate charge-coupled device (CCD) cameras, and slow-scan CCD cameras. SIT cameras require a minimum of 100 pA of beam current passing through the specimen in order to form an image that can be viewed in real time. TV rate CCD cameras require several nA of specimen current for real time imaging or can integrate over time to build-up a sufficiently intense image. Slow scan cameras with large (at least $1\text{K} \times 1\text{K}$) pixels can perform spatial integration on the chip and can output acceptable images at rates faster than produced by TV rate cameras (30 frames per second). State of the art slow scan CCD cameras along with current PC technology (as of 2002) are capable of obtaining and indexing 50 to 60 images per second.

Beam Diameter at Given Voltage and Current: The spatial resolution obtained by a backscatter diffraction system goes as the resolution for other types of imaging in an SEM. Different SEMs can supply the required probe current and voltage with varying beam diameters. In general, field emission sources will have the best spatial resolution followed by LaB_6 and W filament sources.

Long Term Stability of the Beam: An EBSD imaging scan often requires several minutes, and sometimes several hours. Hence, stability of the accelerating potential and probe current are essential for successful imaging over long periods of time. Unstable current results in a drop in image quality or beam drift manifest as distortion in the final computer regenerated image.

Sample Stage

Since the specimen must be tilted at a high angle with respect to the electron beam it is convenient that the stage tilt at least 60° directly towards the phosphor screen normal orientation. In the preferred arrangement, the stage is computer controlled for x - y motion in the tilted position. The SEM stage must be free from mechanical drift that would cause distortion in the regenerated image. In the absence of a computer-controlled stage in the optimal position, a pre-tilted specimen holder can be used with x - y - z motion or with only beam-control scan capability.

SEM Port Configuration

As indicated in the previous section, it is convenient for the stage to tilt toward the phosphor screen. Ideally, this port lies directly opposite the direction to which the stage tilts and its center is approximately equivalent to the centric position of the SEM. Acceptable deviations from this position are about 20° in any direction, vertical or horizontal (see Section 10.2.2).

Simultaneous collection of crystallographic and elemental information over a specimen surface enables correlation of second-phase particles, inclusions, precipitates, etc., with orientation and grain boundary character. As with any electron detector, the position of the phosphor screen (close to the specimen-beam interaction location) will detract from the signal reaching the energy dispersive spectroscopy (EDS) detector. To enable simultaneous operation, the EDS and EBSD detectors must be on the same side of the specimen chamber and must offer as little interference with one another as possible. Positioning the detectors side by side or with the EDS detector directly above the phosphor screen offers the best opportunity for simultaneous data collection.

Mechanical Interface/Phosphor Screens

The interface holds the camera, the phosphor screen, and sometimes the forward scatter detector. It must be retractable so as not to interfere with normal SEM operation and it must insert to place the phosphor screen at the desired position. The ideal position is to have the screen normally positioned horizontally (assuming a vertical beam) with at least 60 degrees angle across the diameter, Φ , of the screen. Acceptable EBSD images will be obtained for $\text{WD} = \pm \frac{1}{3} \Phi$ from the ideal position, and for the screen to be oriented 20° from the ideal in any direction. The ideal phosphor location is shown in the schematic of Fig. 3.

Fig. 3 Ideal position of the phosphor screen in relation to the specimen and electron beam and definition of calibration parameters

The phosphor screen is generally matched to the camera for optimum performance. Common phosphors employed for EBSD applications include P20 and P43. P20 has a short decay time at high current densities, which occurs in photon counting tubes, but long at low-current densities. This latter property is a good match to the eye in direct view low light systems. It is yellow/green emitting at 540 nm and has a decay time of about 1 to 10 ms with an efficiency (lumens/watt) of 30. P43 phosphor is preferred for most applications with TV camera output, because of its efficiency and linearity. It is also fast enough for most high frame-rate applications. It is green emitting (548 nm) with a 1.2 ms decay time and an efficiency of 50. The phosphor must be satisfactorily grounded as a floating phosphor will charge and degrade the performance of the SEM as well as crystal mapping by automated EBSD.

A forward scatter detector is essentially a backscatter detector in the forward scattering position. The utility of this detector is such that backscatter contrast may be obtained while the specimen is tilted in the proper orientation for EBSD analysis. Typical backscatter detectors are positioned on the pole piece and will not function properly at such high tilt angles. Unfortunately, the ideal location for the forward scatter detector is exactly the same as that for the phosphor screen. A compromise is typically made by placing the forward scatter detector directly underneath the phosphor screen and inclined at about a 45° angle facing up at the specimen. The detector may also be placed at either side of the phosphor screen with only minor degradation to the detector response. The reader is referred to Ref. [19] for a discussion on advanced imaging techniques with multiple forward scatter detectors.

Camera System

There are several types of camera systems that can be used for EBSD image detection. Historically, Peltier-cooled CCD cameras and silicon intensified target (SIT) cameras have been used for automated data acquisition, and slow scan CCD cameras for high-quality imaging and phase identification. Depending on the interests of the user, one camera may be preferable. Currently, the slow scan CCD camera may be used for both rapid scan rate imaging and for high quality EBSD image collection. This is the camera of choice, and is not particularly more expensive than SIT or CCD cameras. The larger the pixel size, the more capture area is available for photon collection, and the image can be collected in shorter times or with minimal on-chip pixel binning. TV rate cameras produce images at 30 frames per second. Modern frame grabbers and computing power can translate this into about 15 indexed images per second. The slow scan CCD cameras can produce binned images on the order of ~100×100 pixels at the rate of 60 to 90 frames per second with sufficient light intensity for reliable indexing. The practical indexing limit for slow scan CCD cameras is currently in the range of 40 to 50

images per second, but that number is likely to continue increasing with more powerful computers and optimized image-handling algorithms. The various chips and cameras that are commercially available will not be discussed in this chapter.

Lens-coupled systems typically employ lenses of low *f*-stop numbers that preserve light intensity. Reducing the aperture size will decrease the light intensity, but will also allow for less distortion in the image due to the lens. Typically, distortion is insignificant and the lens is operated at its largest aperture. Also available are camera systems that do not use a lens, but rely on coherent fiber optic bundles attached to the phosphor screen to bring the image to the CCD chip. This preserves the signal level from the phosphor screen and minimizes distortion. This configuration also offers the best signal-to-noise performance in an imaging system.

Brief Overview of the Physics and Mathematics of EBSD

Simply stated, EBSD is a convergent beam technique whereby an electron diffraction pattern is formed by coherently backscattered electrons diffracted by planes matching the Bragg condition:

$$\lambda = 2d \sin \theta$$

where λ is the wavelength of the electron beam, d is the interplanar spacing for a given set of lattice planes, and θ is the Bragg angle. When an electron beam encounters a solid material, it is inelastically scattered in all directions beneath the surface of the material. As a result, there are always some electrons that satisfy the Bragg angle of every plane in the crystallite. These electrons are elastically scattered as they exit the specimen surface to form the contrast observed in EBSD patterns. Because the electrons travel from the source in all directions, the diffracted beams lie on the surface of a cone whose axis is normal to the diffracted plane for each set of planes for which the Bragg condition is satisfied. These cones intersect a phosphor screen placed in front of the specimen and give rise to the pattern. Each pair of cones, whose intersection with the phosphor screen produces a nearly parallel set of lines, is termed a Kikuchi band. The location of intersection of two or more Kikuchi bands corresponds to a zone axis, with major zone axes being positions at which many bands intersect. For a more complete discussion, the reader is referred to Reimer.^[20]

The EBSD pattern as seen on a flat phosphor screen is essentially a gnomonic projection emanating from the specimen-beam interaction position (denoted *O* in Fig. 3). The centerline of each Kikuchi band is the exact geometric projection of the crystallite lattice plane from which the given band was produced. To determine the orientation of the plane normal, a simple cross product is taken between two vectors lying within the plane.

The following discussion refers to the diagram shown in Fig. 4 and follows that of Wright.^[21] A unit vector defining the orientation of the normal to the plane defined by $O-P-Q$ is obtained by:

$$\mathbf{n}_1 = \frac{OP \times OQ}{|OP \times OQ|} \quad (1)$$

and similarly for the plane defined by $O-R-S$:

$$\mathbf{n}_2 = \frac{OR \times OS}{|OR \times OS|} \quad (2)$$

where $||$ denotes magnitude of the vector. The angle between these two planes, θ , is given by the dot product of $\mathbf{n}_1$ with $\mathbf{n}_2$:

$$\cos \theta = \frac{|\mathbf{n}_1 \cdot \mathbf{n}_2|}{|\mathbf{n}_1| |\mathbf{n}_2|} \quad (3)$$

This angle, measured from the EBSD image, corresponds to that dictated by the crystallography of the specimen, where the angle between two planes ($h_1 K_1 l_1$) and ($h_2 K_2 l_2$) is given by

$$\cos \theta = \frac{(h_1 k_1 l_1) \cdot (h_2 k_2 l_2)}{|(h_1 k_1 l_1)| |(h_2 k_2 l_2)|} \quad (4)$$

All possible angles between the various diffracting planes are calculated and the measured angles are compared with those from the ideal crystal lattice in determining the planes from which each Kikuchi band was generated. Zone axes are given by the cross product of any two intersecting Kikuchi bands. An orientation matrix (direction cosine matrix) can be obtained by relating what is known about the specimen geometry with respect to the phosphor screen to the measured crystallite lattice plane normal orientations as represented in both the crystal coordinate frame and in the specimen coordinate frame. One method to accomplish this is to construct an intermediate coordinate frame from the measured lattice

plane normal orientations such as given in Eqs. 1 and 2. One choice of such an intermediate coordinate frame is given below:

$$\mathbf{e}_1^p = \mathbf{n}_1, \quad \mathbf{e}_2^p = \frac{\mathbf{n}_1 \times \mathbf{n}_2}{|\mathbf{n}_1 \times \mathbf{n}_2|}, \quad \text{and} \quad \mathbf{e}_3^p = \mathbf{e}_1^p \times \mathbf{e}_2^p \quad (5)$$

The same coordinate frame as that defined by Eq. 5 can be given in relation to the crystal coordinate frame as:

$$\mathbf{e}_1^{C*} = \frac{(h_1 k_1 l_1)}{|(h_1 k_1 l_1)|}, \quad \mathbf{e}_2^{C*} = \frac{(h_1 k_1 l_1) \times (h_2 k_2 l_2)}{|(h_1 k_1 l_1) \times (h_2 k_2 l_2)|}, \quad \text{and} \quad \mathbf{e}_3^{C*} = \mathbf{e}_1^{C*} \times \mathbf{e}_2^{C*} \quad (6)$$

$\mathbf{e}^s$ contains information of the specimen position relative to the image obtained at the phosphor screen, and $\mathbf{e}^c$ relates the lattice parameters to an orthonormal reference frame (identity matrix for cubic crystallites). Finally, by relating the specimen coordinate frame, to that given by Eq. 5, and the crystal frame to that given by Eq. 6, one obtains the desired expression:

$$g_{ij}^s = \mathbf{e}_i^p \cdot \mathbf{e}_j^s \quad \text{and} \quad g_{ij}^c = \mathbf{e}_i^c \cdot \mathbf{e}_j^{C*} \quad \text{with} \quad g_{ij} = g_{ij}^s \cdot g_{ij}^c \quad (7)$$

The orientation matrix in Expression 7 is in the passive formalism, i.e., it is the rotation required to bring the sample coordinate frame into coincidence with the crystal reference frame.

Automated Band Detection

In order to perform automated EBSD mapping of crystalline materials, an image analysis technique that could identify the positions of the Kikuchi bands was adopted. The Hough transform^[15] or mathematically similar Radon transform^[22] are now used almost exclusively for this purpose. The polar equation of a line may be denoted by:

$$\rho = x \cos \omega + y \sin \omega \quad (8)$$

where the ρ and ω parameters are defined in a Cartesian coordinate frame as seen in Fig. 5. The transform in effect integrates the intensity along all possible straight lines that can be drawn in an image, reducing all lines in real space to a single point defined by (ρ, ω) in Hough (or Radon) space. In the resultant accumulator array, each peak in intensity corresponds to a Kikuchi band that is easily identified. Various convolution masks can be applied in Hough space to optimize band detection. Once the algorithm identifies the position and orientation of the Kikuchi bands, the procedure for indexing and obtaining the orientation of the crystallite lattice is employed as described previously.

Fig. 4 Relative locations of the electron beam-specimen interaction point with the phosphor screen and the Kikuchi bands

Fig. 5 Definition of parameters describing the Hough and Radon transforms

Invariably, some EBSD images will be weak and certain bands may be detected incorrectly, either identifying a band where none exists, or finding the wrong orientation for a weaker band. The measured interplanar angles, whether from actual or improperly identified Kikuchi bands, are compared against a computer-generated list of angles between high-intensity diffracting planes of the crystal type under investigation. Included in the comparison of measured vs. ideal angles is a tolerance value which dictates to within what accuracy the angles must lie in order to be identified as the given set of Kikuchi bands. The orientation of the crystal lattice is generally unique for any triplet of bands (assuming one other point in the image is known, e.g., the pattern center). However, more than a single orientation solution is often obtained from a given triplet of Kikuchi bands. The uniqueness of the solution is determined by a combination of the tolerance angle and the crystal structure of the specimen being investigated. User confidence in the final solution can be measured by a factor that is determined from the number of similar orientations found from a given set of bands. A “vote” is assigned to a given orientation for each set of band triplets satisfying the solution.^[23] The confidence index (CI) is defined by the relationship, $CI = (V_I - V_{II}) / V_{ideal}$ where V_I is the number of “votes” for the first solution, V_{II} is the number for the second most likely solution, and V_{ideal} is the total number of Kikuchi band triplets available. The dependence of the solution reliability on CI for FCC materials has been investigated and it was determined that for images where at least seven Kikuchi bands were identified (correctly or incorrectly), the solution was correct 95% of the time for patterns with a CI of 0.1 or greater. Analysis of good quality diffraction images from the FCC crystal structure commonly result in CI values up to 0.9 with typical values being about 0.7 when seven Kikuchi bands are correctly identified. (Notice that if only three bands are detected and one solution found, the CI would be 1.0 even for an incorrect solution, which is the reason for the caveat that the number of bands identified must be included.) Fig. 6 shows the results of this study. The investigation was performed by placing the electron beam on a single

Fig. 6 Confidence index vs. fraction of correct solution for poor quality EBSD images assuming that at least 6 Kikuchi bands are identified

crystal of very poor image quality. The temporal variability in the image sometimes allowed the incorrect solution to be obtained due to improper identification of diffraction bands. The analysis was performed 100 times consecutively for five different single-crystal orientations and the data were accumulated in obtaining Fig. 6. The percentage of solutions correct for a CI of 0 is often greater than zero. This is because even when two solutions receive the same number of votes, the solution that has the smallest angular deviation from the theoretical value is chosen and is often the correct solution for poor quality images.

EBSD Image Calibration

For the proper orientation of the crystallite lattice planes to be determined, the pattern center relative to the phosphor screen must be accurately known. Pattern center is defined as the position of the specimen-beam interaction point in coordinates of the phosphor screen. These are typically identified by the triplet (x^* , y^* , z^*) where x^* and y^* are positions seen in the plane of the phosphor screen, and z^* is the specimen to screen distance along a line normal to the plane of the phosphor. The working distance of the SEM also comes into play in determining how the calibration changes with beam motion, and is generally tracked as a calibration parameter. The schematic given in Fig. 3 shows the definitions of the calibration parameters for the pattern center in relation to the specimen, electron beam, and phosphor screen.

Accuracy of the pattern center calibration is important in determining the correct orientation of the crystallite. The exact amount of error incurred depends upon the specimen to screen distance. The longer the distance, the less the error will be in determining the plane normal orientation. For example, consider a given Kikuchi band as shown in Fig. 7, and assume that the vector n_i shows the true orientation of the corresponding plane normal. The actual plane projection is that indicated by the finely spaced hatching

Fig. 7 A schematic view showing the dependence on specimen to screen distance of the error in orientation determination as a function of pattern center position

lines. If the pattern center were defined improperly and was assumed to be at the lower position shown, the calculated plane normal orientation would be that shown by n_2 . If the specimen to screen distance is relatively long, the error introduced by the erroneous pattern center is small. In contrast, if the specimen to screen distance is short, as shown on the right-hand side of Fig. 7, the error in determining the proper plane normal orientation could be relatively large. As can be imagined in a thought experiment, the actual error will depend on the orientation of the plane in question. If the actual pattern center and an incorrectly identified pattern center lie along a given Kikuchi band in the plane of the phosphor, there will be no error in determining the orientation of that single plane regardless of the magnitude of error in pattern center determination. The primary difficulty associated with improper pattern center calibration is that the interplanar angles will be erroneously determined, and the incorrect indexing will be assigned to the bands. For typical specimen to screen distances (~ 20 mm), screen diameters (~ 40 mm), and image sizes on the order of 500×500 pixels, the pattern center must be determined to within about 15 pixels (3% error), as a rule of thumb, for acceptable indexing and orientation determination. Calibration techniques will not be discussed in this chapter as modern EBSD systems typically employ self-calibration strategies that iteratively fit the best solutions to the bands identified by the image analysis algorithm and the user-input definition of crystal structure. A complete discussion of calibration techniques for EBSD analysis can be found in the reports by Day^[24] and Krieger-Lassen and Bilde-Sorensen.^[25]

MULTI-PHASE ANALYSIS

For aluminum metallurgy, single-phase analysis is often adequate for orientation mapping, but the large majority of engineering materials are not composed of a single phase. The investigation of multi-phase structures offers a series of complexities to the automated EBSD technique. Among the difficulties presented by these materials are the ability to distinguish between different phases and experimental deficiencies in imaging diffraction patterns from multiple phases within a single specimen. Many researchers have published data on multiphase materials obtained by automated EBSD techniques with good results.^[23,26–31]

Phase Discrimination

When several known phases exist in a single specimen it is trivial for the researcher to include all such phases for indexing consideration during automated EBSD analysis. The indexing algorithms are generally adequate for distinguishing between phases whose Kikuchi bands are sufficiently distinct in terms of interplanar angle. Typically, the indexing algorithm will check all phases that the researcher has included as possible, and will perform a “best-fit” to the phase that most closely matches the geometry of the detected bands. Modern PC computers can perform such analysis over several candidate phases without paying a time penalty over that required for the next image to be obtained by the imaging system.

A practical challenge in multi-phase analysis is that the “background” image used for enhancing the EBSD image may vary significantly from one phase to the next. This problem is adequately addressed in a manner similar to that described for enhancing Kikuchi diffraction images from the TEM.^[32] The technique involves using a smoothed or filtered version of each individual EBSD image to correct for the intensity gradients and enhance contrast. This can be performed either from software routines or by hardware solutions where the video signal is split into two equivalent signals. One of the signals is filtered for use as a background image in enhancing the original signal.

Additional challenges exist with many multi-phase materials. The most common, and sometimes insurmountable, of these is the ability to obtain good diffraction images from all phases. Specimen preparation techniques are generally optimized for viewing specific features of the microstructure and it is often difficult to have all phases prepared satisfactorily for EBSD analysis. A final mechanical polish using $0.05 \mu\text{m}$ colloidal silica solution often affords the best opportunity for successful mapping of multiple phases.

Another challenge is that some phases are indistinguishable from one another using EBSD techniques. For example, because of uncertainties in measuring inter planar angles, a cubic phase cannot be readily distinguished from a phase that has a tetragonal distortion of 1 to 2%. The minimum resolution for such analysis is a function of the phases themselves and of the ability for the image analysis algorithms to measure accurately the angles between

Kikuchi bands. A host of materials problems fall into this category. Modified image analysis routines are sometimes employed in an attempt to overcome this challenge by tightening the tolerances of the Hough transform accumulator array.^[22,33] A similar problem occurs when phases are distinguished only by the addition or deletion of low-intensity diffracting planes. These low-intensity planes are difficult to detect by the image analysis algorithms, and are typically ignored in EBSD analysis. Such bands in the Kikuchi pattern can only be observed by using imaging apparatus that obtains very high-quality diffraction patterns,^[18] and from specimens that are ideally prepared.

A simple example of two-phase analysis is shown in Figs. 8 and 9. Figure 8 is a secondary electron image of a region of retained austenite in a ferrite matrix. The FCC and BCC phases are easily distinguishable because of the different planes on which diffraction occurs. Figure 9 shows a phase map obtained by orientation imaging techniques of a similar specimen. The fraction of retained austenite measured by automated EBSD analysis was 0.12, compared with about 0.11 by conventional line scan analyses.

It is apparent from the discussion above that several challenges remain in the analysis of multiphase alloys. Several materials of multi-phase composition, however, can be analyzed with the current EBSD technology. The example problem discussed, that of retained austenite in a ferrite matrix, is a simple experimental example, but readily demonstrates the power of the technique.

Phase Identification

Phase identification using EBSD^[18,34–37] follows the same principles as discussed in the section on phase discrimination. The difference is that there are potentially no candidate structures available for the researcher to consider

Fig. 8 Secondary electron image of a specimen of retained austenite in a ferrite matrix

Fig. 9 Automated EBSD map of the same structure as that seen in Fig. 8. Dark shading indicates ferrite. The scale bar shown is 12 μm

prior to imaging by EBSD techniques. To obtain candidate structures the researcher typically identifies the local chemistry of the beam position by EDS analysis of the regions. This can be performed simultaneously with the EBSD system communicating directly with the EDS system to obtain elemental information. Once the chemistry of the phase is known, databases such as those available from the International Center for Diffraction Data (ICDD)^[38] can be interrogated to obtain a list of candidate phases. From these candidate phases, the correct solution can be obtained from the geometry of the Kikuchi bands as described in the section on phase discrimination. A second criterion that can be used to decrease the number of candidate phases (in addition to chemistry) is direct measurement of the unit cell volumes from the EBSD patterns.^[37] It is possible to perform such phase analysis on a point-by-point, interactive basis, as well as in automated scanning mode on most systems.

Attempts to perform phase identification by EBSD analysis of materials with unknown chemistry, or phases that are not included in a database, are hindered by the inability to accurately measure the interplanar spacing (d -spacing) of a given family of diffracting planes from the diffraction patterns. The d -spacing of a plane producing a given Kikuchi band can be determined experimentally by measurement of the bandwidth angle, β . β is defined as the angle formed by line segments that originate at the point of specimen-beam interaction and terminate at either side of a given Kikuchi band along a line normal to the

Fig. 10 Schematic showing the definition of the band-width angle, β

band and passing through the pattern center in the plane of the phosphor. The schematic shown in Fig. 10 illustrates the band-width angle definition. (3 is given analytically by manipulation of Bragg's law:

$$\beta = \sin^{-1} \left(\frac{\lambda}{2d_{hkl}} \right) \quad (9)$$

As electron beam energy increases, the wavelength of the electron beam, λ , becomes smaller and β decreases meaning that the observed band-widths become smaller.

With a priori knowledge of the pattern center position and specimen to screen distance, β can be measured directly from the Kikuchi pattern. The uncertainty in the measurement of β is a function of pixel resolution of the imaging system and fraction of the image spanned by the Kikuchi band. The most accurate d -spacing measurements are therefore made from large specimen to screen distances, and low energy of the electron beam. These conditions are poor for high accuracy orientation determination since the measurement of interplanar angle spacing is less accurate, and there are fewer Kikuchi bands evident in the EBSD image (because there is less solid angle).

Recent work has adopted the approach of examining higher-order Laue zone (HOLZ) rings to aid in determination of the d -spacings.^[37] HOLZ rings are observed around certain zone axes of many materials such as the EBSD image from a Si single crystal shown in Fig. 11. The HOLZ ring approach will decrease the uncertainty in d -spacing measurement, thereby increasing the number of phases that can be accurately identified using EBSD. There are challenges associated with the technique such as the fact that not all materials produce readily identifiable HOLZ rings in EBSD images. Additionally, there are dynamical diffraction effects that may or may not be important depending upon the material and the specific zone axis in question that also introduce uncertainties into the analysis.

APPLICATION TO AL INTEGRATED CIRCUIT INTERCONNECTS

The continuing miniaturization of integrated circuits is placing ever-increasing demands upon the materials and

Fig. 11 EBSD image produced from single crystal Si at a beam energy of 20keV. HOLZ rings are apparent as ellipses or circles around major zone axes

processes used in IC fabrication. Maximum current densities in high performance ICs are approaching and even eclipsing 10^6 A/cm², and the thrust towards further reduction of the minimum feature size of the interconnects continues. The Semiconductor Industry Association's National Technology Roadmap for Semiconductors^[39] indicates that future interconnect fabrication is "the technology thrust with the largest potential technology gaps." Of primary concern are fabrication procedures capable of meeting strict critical dimension tolerances. In addition, reliability of interconnects and their resistance to stress voiding and electromigration presents considerable challenges in future generations of ICs.

Both stress voiding and electromigration processes are known to depend upon the interconnect line microstructure.^[40–44] For current and future generations of interconnects, reliability is a function of specific microstructural features instead of just the average properties of the metal. These include alloying effects, grain size, and crystallographic texture, among others. The electromigration rate is controlled by the diffusive properties of the interconnect line microstructure. Diffusion occurs through the bulk material, along grain boundaries, and along metal/oxide interfaces. An empirical relationship for the mean time to failure (MTF) of an aluminum based interconnect line as a function of grain size and crystallographic texture was given almost two decades ago by Vaidya and Sinha:^[40]

$$\text{MTF} = k(S/\sigma^2) \log \left[I_{(111)}/I_{(200)} \right]^3 \quad (10)$$

where $I_{(111)}$ and $I_{(200)}$ are the orientation densities of the (111) and (200) texture components respectively. S is the mean grain size, σ is the standard deviation of the lognormal grain size distribution, and K is a material constant.

This relationship can be explained by the fact that a strong texture will limit the range of grain boundary and surface structures in the material. Such grain boundaries are thought to lie in stable, low energy, configurations.^[45] In addition, the homogeneity of geometric structure allows for the properties to be constant throughout the interconnect line. This reduces the frequency of local incompatibility and stress concentration due to material build up which is more pervasive in materials with randomly oriented structures. Until recently it has only been feasible to measure crystallographic texture using x-ray diffraction techniques. The grain boundary character and local structure inhomogeneity of the interconnect lines was intractable except by tedious transmission electron microscopy (TEM) procedures. The subject of this section is to discuss the application of automated EBSD techniques in IC interconnect process design and quality control. The focus of the discussion is upon Al-based interconnect lines; with a brief introductory section on application to Cu damascene lines.

Experiments and Results

The following sections briefly discuss four different experiments that were performed to investigate the microstructure/electromigration performance relationship and structure evolution and optimization.

Comparison of Microstructures and MTFs in Al-Cu

Mean time to failure (MTF) during accelerated testing of IC interconnect lines is a common measure in specifying resistance to electromigration processes. The stacking sequence of metal layers which results in long times to failure for Al based interconnect lines is well known. Thin layers of Ti and TiN deposited on SiO_2 before the Al deposition results in films exhibiting strong (111) textures and generally long times to failure. Two Al-0.5% Cu films that produce interconnects with known MTF behavior were analyzed. The first film, which is hereafter referred to as the high MTF film, was processed using Ti and TiN sublayers and was tested to have an MTF that was an order of magnitude higher than lines from the second film. The second film (low MTF film) incorporated no metal sublayers so the Al-Cu alloy was deposited directly on the SiO_2 .

Automated EBSD analysis was used to investigate the structure of the films.^[46] The lines themselves were not analyzed in this study, but the microstructure of the films is assumed to be representative to that in the lines that were tested. Figure 12 shows orientation images color-coded according to the crystallographic pole aligned normal to the specimen surface. The orientation color key is shown

as the inverse pole figure seen. Both films are observed to have a preponderance of (111) oriented grains, but with a significantly higher distribution in the high MTF film. Texture in metal films is typically characterized by x-ray rocking curves. The standard measure derived from rocking curves is the full-width half-maximum (FWHM) value of the (111) diffraction peak. The FWHM values of the two films as measured by x-ray diffraction are 6.1° and 26.5° for the high and low MTF films respectively. Figure 13 contains a comparison of the reconstructed rocking curves as derived from the EBSD measurements. The FWHM values as determined by EBSD scans are 5.33° and 27.78° that compare favorably with those obtained by standard x-ray diffraction techniques. Knorr^[47] stresses that the rocking curve technique is insufficient and that complete pole figures should be measured for proper texture characterization of thin films. Pole figures were not measured using x-ray diffraction. Automated EBSD data, on the other hand, inherently contain the complete information to determine the crystallite orientation distribution function (ODF) from which all pole figures are readily derived. This is because x-ray diffraction measures only the orientation of lattice planes, while electron diffraction yields the three-dimensional character of the orientation. The (111) pole figures for the two films are given as Fig. 14.

Additional information, which is not available from x-ray measurements, can be obtained from the EBSD data such as the grain size distribution. In addition, clustering of orientations and the character of grain boundaries is retrievable from the data. In a strongly (111) textured film, all grain boundaries are (111) tilt boundaries and can be reasonably described using only the misorientation angle. The misorientation angle histogram, shown in Fig. 15, contains the distribution of minimum angles by which neighboring crystallites can be rotated into coincidence with each other. As seen in the distributions, the high MTF film contains a high fraction of low angle boundaries that are not observed in the low MTF film. These low angle boundaries are low energy and positions of relatively slow diffusion. The presence of these boundaries is a result of clustering of crystallites with similar orientations (both in plane and out of plane). It is reasonable to argue, then, that the improvement in MTF for the strong textured film is a result of the grain boundary character imposed by the texture and of the orientation clustering which occurs. Using EBSD it is feasible to measure statistically reliable distributions of grain boundaries, whereas such information was not previously available.

Investigation of Pure Al Films Deposited by the PIB Technique

Partially ionized beam (PIB) deposition was used to deposit Al films having identical stacking sequences and similar grain sizes, but widely varying electromigration characteristics.^[48,49] High purity Al was deposited

on oxidized silicon wafers with an rf-sputtered TiN wetting layer. There was an ion to atom ratio of about 6%. The ions were accelerated by potentials of 0, 3, and 6kV applied to the electrode located near the substrate. The resulting films are hereafter referred to as the 0, 3, and 6kV films. Average drift velocities were measured in 8mm wide lines tested under electromigration conditions. All the experiments were carried out in atmosphere at a temperature range from 250 to 360°C. The lines were stressed by a current density of 6×10^5 A/cm². The edge displacement was measured by standard optical and electron optical microscopy techniques. The electromigration activation energies for the three deposition conditions were determined to be 0.33, 0.52, and 0.88 eV, respectively, for the 0, 3, and 6kV films. Therefore, it is expected that MTF would increase with increasing accelerating potential.

The structures were analyzed by EBSD and found to have relatively weak (111) textures. The 0kV film possessed the strongest texture with about 5.2 times random (111) intensity. The values for the 3 and 6kV films were 3.07 and 2.92 respectively. These measurements indicate that the film with the strongest (111) texture has the shortest life expectancy. This is obviously contrary to the conventional wisdom discussed above. Analysis of the grain

boundary structure of these films reveals that the poorest textured film deposited using a 6kV potential contained a large fraction of low angle grain boundaries which was not present in the 0kV film. In addition, both the 3kV film and the 6kV film had a relatively high fraction of “special” boundaries as classified by the coincident site lattice (CSL) theory.^[50] Some research suggests that a high fraction of CSL boundaries correlates with longer lifetimes for Al interconnects.^[45]

Structure Evolution as a Function of Line Width for RIE and Damascene Processed Lines

Crystallographic structure and grain boundary character was investigated as a function of line width for Al-0.5%Cu lines processed using conventional reactive ion etching (RIE) and for lines fabricated using the damascene process.^[51] RIE processed lines having widths from 4 to 0.5 μ m were fabricated from 1 μ m thick films. These Al-Cu films were deposited on Ti and TiN sub-layers and the resulting structure exhibited a very strong (111) texture ($\sim 2.5^\circ$ FWHM). The patterned structures were analyzed by orientation imaging following a post-patterning anneal. No passivation was applied to the wafer. It was determined from the EBSD measurements that (111) texture strength increases with decreasing line width as a result of structure evolution during the anneal. It was also found that the fraction of low angle grain boundaries increases with decreasing line width. Finally, a weak in-plane texture component develops in the narrow, bamboo-structured lines, such that the (110) plane preferentially aligns with the grain boundary plane. The difference in structure between wide and narrow lines occurs during grain growth that takes place during high temperature deposition of the passivation layer. In this case the structure was annealed at 370°C for 15min to simulate the fabrication process.

The results of texture analysis were reversed for the damascene process fabricated lines as compared with the RIE lines. Trenches in the SiO₂ layer 1 μ m deep were

coated with Ti and TiN layers before sputtering with Al-0.5 wt%Cu. Details of the damascene processing are given elsewhere.^[52] Lines having widths from 8 to 0.5 μm were investigated. The texture was relatively strong in the wide lines as compared with the weak texture observed in the narrow lines. This result has also been observed by researchers from IBM.^[53] The 0.5 μm lines contained a significant (001) texture component as well as the (111) component observed in all line widths. Analysis of the grain boundary structure revealed that in the near-bamboo structured 0.5 μm lines, the (110) plane preferentially aligned itself with the grain boundary plane for both the (111) and the (001) oriented grains. This is the same preferred grain boundary structure as that observed in the strongly textured narrow lines fabricated using RIE technology, even though the texture results were significantly different. Electromigration testing of the lines showed virtually no decrease in the performance of the damascene lines as compared with those processed by RIE.

A second study was performed on unpassivated RIE fabricated lines wherein orientation imaging was employed to observe grain growth in situ in the SEM chamber. Wide lines of 5.0 and 1.5 μm were investigated. Observations were made after one hour anneals at 350, 400, 470, and 530°C for each set of lines. Secondary electron images of the wide lines after the 350 and 530°C anneals are shown as Fig. 16. Significant thermal grooving occurred during the 350°C anneal. These grooves persisted after the 530°C anneal without noticeable evolution. The thermal grooves did not pin the grain boundaries, however, as evidenced by the orientation maps. Figures 17 and 18 contain the orientation images of the wide and narrow lines respectively, showing the progression of grain growth. All grains were within a few degrees of having the (111) plane lie in the plane of the wafer. The colors of the grains indicate orientation

Fig. 16 Images showing surface grooving subsequent to the 350°C anneal (on the left) and after the 530°C anneal (on the right)

Fig. 17 Final structures of the 5.0 μm lines after grain growth

Fig. 18 Final microstructures of the 1.5 μm lines after grain growth

Fig. 19 Orientation density (times random ODF value) for the (111) texture component

along the line direction. The color key shown in Fig. 12 indicates colors to which the various orientations correspond. Similar results were observed to those suggested by the study described in the previous paragraph. The texture was stronger in the narrow lines than in the wide lines and strengthened with each annealing step (see Fig. 19). In

addition, the fraction of low angle grain boundaries was higher in the narrow lines than in the wide lines and also increased with grain growth for both line widths observed.

The majority of the grain boundaries in the 1.5 μm lines became bamboo-like in nature after the series of annealing treatments. Approximately twenty boundaries, or portions of boundaries, survived annealing without becoming bamboo-like in nature. Of these twenty, all but three were low angle boundaries, which implies that they were in a low energy, stable configuration. The other three were each observed to be symmetric tilt boundaries sharing either a (211) or a (321) crystallographic plane aligned with the grain boundary. Symmetric tilt boundaries have been observed to be stable in other investigations of grain growth in thin films.^[54]

Analysis of Cu Damascene Lines

At present, the most common application of orientation imaging for investigation of interconnect lines is in connection with Cu damascene structures. The nature of texture within the trenches is significantly different than in the blanket films, and cannot be easily observed using x-ray diffraction. It is known that the coherent twin boundary in FCC metals is a low energy boundary that lies in a stable configuration. Diffusion along such a boundary would be very slow compared with a random, high-angle grain boundary. It follows that a large number of twin boundaries in the structure may improve electromigration resistance of the interconnect line and reliability of the integrated circuit.

EBSD has played an important role in numerous studies of electromigration and Cu damascene process optimization.^[55–60] Further research into the influence of sub-layer chemistry and deposition technique on the resulting structure and the ultimate effect on manufacturability and reliability is ongoing. It is likely that EBSD will continue to be an important part of the research effort into defining process parameters for the Cu damascene technique.

Discussion

Each of the analyses discussed above shows methods whereby EBSD is used to investigate mechanisms controlling interconnect reliability. The fact that EBSD is capable of replacing currently employed techniques for monitoring the crystallographic texture and grain size distributions leads one to the conclusion that it will continue to be a valuable tool in research of metallization processes for IC fabrication. The added information obtained during EBSD analyses of grain boundary structure and orientation correlations is also likely to become increasingly valuable as demands upon the optimization of interconnect microstructure require more predictable performance.

APPLICATION TO FRICTION STIR WELDING OF ALUMINUM

A relatively new friction welding process called friction stir welding (FSW) was developed and patented in the early 1990s,^[61] and has become an important industrial joining process. The advantages of FSW over conventional fusion welding have been recognized by many researchers, particularly for industries that rely heavily on joining aluminum alloys,^[61–70] and numerous symposia and international conferences have been held to discuss the subject. Many researchers have adopted the EBSD technique to investigate the microstructure developed during FSW (see Appendix 2). A few significant advantages in the manufacturing of aluminum structures include the elimination of cracking in the weld fusion and heat-affected zones (HAZ), weld porosity, filler metals, shielding gases, and costly weld preparation. Despite these potential benefits, there remains a vast amount of research and development needed to better understand the microstructure and long-term service integrity associated with friction stir welds. An understanding of microstructural evolution during FSW and the mechanisms by which the associated microstructures affect such mechanical and physical properties as fracture strength, fatigue, creep, and corrosion is critical.

The heterogeneity of fracture in the weld metal and heat-affected zones is a function of precipitate volume fractions and distributions that are directly dependent upon grain boundary diffusivity. Grain boundary diffusivity is, in turn, proportional to the grain boundary energy and dependent upon the crystallographic structure of the boundary. Boundaries with low energy configurations will typically have low diffusivity, which retards the formation and growth of detrimental precipitates on crystallite interfaces. Spatial gradients of the texture likely delineate regions of varying grain boundary structure. In addition, deformation response, corrosion susceptibility, surface appearance, and various other material properties are inhomogeneous in nature as a result of spatial variations in crystallographic texture. Automated EBSD analysis offers precise information on local textures and grain boundary structures that is invaluable to researchers of FSW. The following discussion is based on Ref. [70].

Experimental Details

Friction stir welds were performed and analyzed in 1100 Al alloy. For the analysis contained in the present discussion, 1100 Al plate, 6.35 mm thick, was sectioned into 10 cm wide by 61 cm long test plates and the edges were machined flat. Welding was performed using a tool that consisted of a 19 mm diameter shoulder with a 6.25 mm diameter right hand threaded pin tool that was approximately 6 mm in length. The plates were aligned such that the weld traveled along the rolling direction (RD) of the plate material and penetrated through the normal direction

(ND) of the processed plate. All welds achieved full penetration with no observable voids or defects. Welds were performed using a rotational speed of 700rpm and a travel rate of 18cm/min, or a rotational speed of 1200rpm and a travel rate of 58 cm/min.

Orientation imaging analysis was performed on entire weld regions on cross-sections of the welds. In addition, plan view orientation images were from near the shoulder, at mid-thickness, and on the bottom face (under the tool pin). The shoulder and mid-plane regions were prepared such that the outward normal to the prepared surface was the surface from which the welding tool entered. The section near the pin bottom was taken very near the bottom surface of the plate. It was prepared by polishing the back-side of the plate so that the outward normal to the polished surface pointed away from the weld tool. This was done to avoid the difficulties in preparing a large thin section as data were taken within about 50 μm of the original surface. A schematic view of the weld geometry and the associated analysis planes is given in Fig. 20.

Orientation images from the large cross-sectional regions were made using 40 to 60 μm steps over areas of approximately 20mm by the plate thickness and the plan view sections employed step sizes from 24 to 40 μm over regions of approximately 4 mm $\times$ 12mm. The resultant grain size is much smaller than the step size used on these sections so only global trends in crystallographic texture can be observed from these scans, and no information is obtained on grain boundary structure. In addition, smaller step sizes were employed in various regions to obtain local information on grain size and micro-textural distributions. A representative orientation image from a complete cross-section of 1100 Al is shown in Fig. 21. Orientations are colored according to the color key shown where the shaded pole is that aligned with the original surface normal orientation of the plates. In all cases, the cross-sections

Fig. 20 A schematic representation of the friction stir weld geometry and the associated analysis planes. Plane 1 (the shaded region) shows the cross-section analyzed, and plane 2 indicates the plan-view geometry. Plan view images were taken at the top, middle, and bottom planes as indicated in the view on the right

Fig. 21 A representative orientation image from a complete cross-section of 1100 Al joined at 700rpm and 18cm/min. The color key shows poles aligned with the normal direction of the plate

were taken so that the weld direction was into the surface of observation, with the advancing side of the weld on the right and the retreating side on the left-hand side of each figure. For the plan view sections analyzed, the advancing weld direction is vertical up in the images shown with the advancing side on the right side and the retreating side on the left. For the bottom section only, where the plate was flipped over for the analysis, the weld direction is up and the advancing side is to the left.

Results

As seen in Fig. 21, strong gradients in crystallographic texture can be observed through the stir zone of the weld nugget. The local texture and the texture gradients offer information on the deformation history of the material in that region. Various zones throughout the weld were isolated and analyzed independently in an attempt to identify recognizable deformation textures that might indicate the local deformation state responsible for producing the given texture. Some of these textures will be shown and discussed in the following paragraphs. Figure 22 shows a

Fig. 22 Orientation image of a region within the weld nugget showing the equiaxed grain morphology and the low angle boundaries resulting from dislocation structure within some of the grains

high magnification orientation image of a region within the nugget of a weld in commercial purity aluminum. The image was taken from a cross-section of the weld and is constructed such that misorientations greater than 15° between neighboring points have a thick boundary, and those from 3° to 15° have a thin boundary line. The average grain diameter, for grains defined by 10° misorientation or greater, was $6.5\text{ }\mu\text{m}$. From this image it is apparent that the grains in the heavily deformed weld nugget region have recovered and/or recrystallized to some extent. The low angle misorientations (narrow lines within the grains) observed within several of the grains is evidence of continued deformation subsequent to recrystallization. Various researchers suggest that the structure dynamically recrystallizes during the joining process.^[63,65,66,68] These observations appear consistent with the structure revealed in the orientation images. The grain boundary structure of the weld nugget varies only slightly from position to position within the equiaxed, recrystallized grain region.

A misorientation angle histogram of a region similar to that seen in Fig. 22 is presented in Fig. 23. The overall distribution is similar to that expected for a random texture as given by Mackenzie,^[71] with the exception that a higher fraction of low angle boundaries exist (due to the dynamically recrystallized structure). This differs from similar plots presented by other researchers: for instance Jata and Semiati^[68] showed a uniform (flat) distribution, indicative of a fiber texture, and Mishra and Mahoney^[72] presented a distribution with virtually no low angle ($< 20^\circ$) boundaries. The differences are likely attributable to a larger area being analyzed in the present study to obtain the data presented in Fig. 23 compared with previously reported results. This indicates that the grain boundary character distribution is likely very different from position to position in the weld nugget and thermomechanically affected zone (TMAZ).

There are various graphical presentations of orientation data that could be adopted in presenting the following results, including pole figures, Euler angle space

Fig. 23 Misorientation angle histogram for a large region within the weld nugget of an 1100 Al alloy

Fig. 24 Plan view orientation images of a FSW joining 1100 Al plates at 700rpm and 18 cm/min. Column (a) colors poles aligned with ND and column (b) colors those aligned with TD in the plates. The advancing side is on the right for the top and mid-planes and on the left for the bottom plane. Orientations are colored according to the color key shown in Fig. 1

projections, Rodrigues vectors, quaternions, etc. For our purposes, it is most instructive to present the distributions as (111) pole figures with the specimen coordinate frame being defined by the normal direction (ND), the weld direction (WD), and the advancing side (AS) of the tool. The axis coming out of the page is the free surface of the plate, and that going into the page is the surface that lies against the backing plate or anvil. All pole figures presented herein follow this convention unless otherwise stated in the text. In addition, all orientation images presented in the following are colored to indicate poles aligned with the normal to the free surface of the plate unless otherwise stated.

The following includes a discussion of the weld textures determined from the plan-view sections of welds. Figure 24 contains orientation images of all three plan-view sections of a weld, with orientations colored according to the normal direction of the plates in column (a) and according to the transverse direction of the plates in column (b). Orientations are colored according to the color key shown in Fig. 21.

Top Plane, Under Tool Shoulder

As with all regions throughout the weld and TMAZ, the texture near the top of the plate and just under the rotating shoulder exhibits significant heterogeneity and gradient structure. Analysis of the texture from the weld cross-sections in this region yields two dominant texture components normal to the plate surface. These are the (111) and (100) components, both of which appear as fiber textures, the (111) fiber being very strong in comparison to the (100). Such textures are reasonable considering that a (111) fiber in the shearing plane caused by the shoulder rotation is the A fiber expected from shear deformation. The (100) component is typical of uniaxial compressive deformation that certainly exists during the friction stir welding process.

Examination of the orientation image of the top plane, colored according to poles aligned with the TD, seen in Fig. 24b, reveals a strong cross-width texture gradient

from the retreating to the advancing side of the weld. This texture gradient is seen in the series of (111) pole figures shown in Fig. 25 that were measured from data segregated into narrow sections along the weld direction. Figure 25c shows the texture of the mid-width region just under the tool shoulder. The dominant orientation is a (111) plane that is aligned at 70° from the normal pointing toward the direction of the advancing weld. Two primary orientations contribute to this 70° (111). First, there is a (111) pole aligned with ND whose (110) direction aligns with TD. In addition, a (411) ND component exists that shares a close proximity to both the 70° rotated (111) and the (110) AS directions with the (111) ND orientation. Analysis of the texture in regions towards the retreating or advancing sides of the weld reveal identical components, but the 70° (111) dominant orientation rotates to be aligned with the radial position of the tool shoulder as it leaves that section of material. Figure 25 shows the spatial arrangement of this feature in consecutive adjoining sections across the weld. The dominant shear direction is a (110) that aligns everywhere tangent to the trailing edge of the tool shoulder. Faster tool feed rates and rpm tended to extend the influence of this texture feature through the thickness of the weld nugget with the exception of the very bottom of the weld.

Fig. 25 Series of (111) pole figures showing the texture gradient across the width of the weld from the retreating to the advancing edge (a–f respectively), just under the tool shoulder

Mid-Plane

In marked contrast to the cube and Goss textures observed in the base metal, the texture in the weld nugget at the mid-plane is a strong (111) component aligned with ND. This is apparent in the orientation image of Fig. 24a where the mid-plane ND image appears as mostly red (100) on either side and primarily blue (111) through the middle 6.5mm or so of the weld. An additional component reveals an in-plane orientation preference, with a 70° (111) RD (WD) rotated component on either side of the weld as shown in Figs. 25e and 26b. The advancing side contains the stronger in-plane texture preference with the dominant (111) plane pointing toward the weld center and up 20° toward the shoulder of the weld tool. The retreating side contains a minor (111) component oriented toward the weld center and 20° up toward the tool shoulder, in mirror fashion to that seen on the advancing edge.

The texture in the mid-plane section varied considerably with weld parameters (feed-rate and rpm) as evidenced by observations from cross-sections through the welds. For example, contrasting results from the tests performed in 1100 Al are shown as (111) pole figures in Fig. 27. Figure 27a shows the texture from the 700rpm, 18cm/min specimen and Fig. 27b shows that from the

Fig. 26 Series of (111) pole figures showing the texture gradient across the width of the weld from the retreating to the advancing edge (a–f respectively), at the mid-plane through the thickness of the weld

1200rpm, 58cm/min weld. The reference frame for the 1200rpm weld was rotated 90° about the WD. The typical A and B partial fiber texture components^[73] are seen for both welds, but the shearing plane is rotated 90° from one another. Both textures indicate a shearing direction along the weld direction (tangent to the edge of the pin), but the slower rotation speed and feed rate shows the dominant shear plane to be normal to the tool axis, and the faster rotation and feed rate has a shearing plane defined by the tool axis and weld direction. This result may be indicative of the extended influence of the shearing caused by the tool shoulder under hot weld conditions.

Bottom Plane, Under Tool Pin

The textures (shown in Fig. 27) at the bottom of the welds, under or near the bottom of the tool pin, consist of partial A fibers with the shear direction being tangent to the weld tool, and the shearing plane being roughly normal to the radial outward direction of the tool. A strong delineation exists, however, between the advancing and retreating sides of the weld. On the advancing side, the shearing plane normal points slightly toward the surface from which the tool enters (and toward the advancing side), and the shear plane normal is oriented away from this surface on the retreating half of the weld. Moving outward from center, the textures evolve consistently to the edges of the analysis region where they are identical on both the advancing and retreating sides of the tool. The textures observed at these edge locations are not those observed from the base metal, as was seen on the mid-plane section. The textures at 4mm from the weld center on the bottom plane section are close to those expected from an ideal shear texture with the shearing direction lying along the weld direction and the shear plane normal in the plane defined by the tool axis and the weld direction. This texture is consistent with that reported for the recrystallized structure near the surface of a rolled Al sheet.^[74] Since the base metal consisted primarily of recrystallization texture components, it is reasonable to assume that the structure seen at the far edges of the area of observation is representative of the base metal surface layer.

Fig. 27 (111) pole figures showing textures of the pin retreating side for (a) the 700rpm, 18cm/min weld, and (b) the 1200rpm, 58 cm/min weld

Conclusions

Severe gradients in crystallographic texture exist through the thickness and across the width of FSWs. These textures can generally be characterized as one or more of the ideal FCC shear textures. The most severe textural gradients exist in the center of the weld at the weld floor, and along the advancing side of the tool through the thickness of the plate. Two planes of strongest shearing are identified as that directly beneath the tool shoulder and normal to the axis of the weld tool, and that inclined 70° from this position outward radially from the tool center. The preponderance of the 70° rotated texture component is somewhat of a mystery and remains a subject of further research and modeling.

The character of local textures through FSWs appears to be largely alloy independent. Only minor differences were observed that could not be explained by weld tool rotation and feed rate. The primary texture difference observed as a function of weld parameters was the plane of shearing on the retreating side of the tool as it changed from normal to the tool axis to aligned with the tool axis at the higher rotation and feed rates. The direction of shearing in this location remained constant with increasing rotation and feed rates, aligned with the direction of weld travel. It is expected that differences in weld tool geometry will result in microtextural differences that must be investigated using EBSD techniques.

APPLICATIONS TO DISLOCATION STRUCTURE OBSERVATION IN ALUMINUM

Since the inception of dislocation theory as applied to plasticity of metals in the 1930s,^[75] researchers have investigated the relationship between dislocation dynamics and the constitutive behavior of metals. Direct observation of dislocation structures by transmission electron microscopy (TEM) has led to the development of substantial new models of plastic deformation, recovery, and recrystallization. However, the relationship between dislocation cell morphology and the plastic behavior of materials is not well understood. A number of models have been derived with varying degrees of success, but these have generally been formulated without a significant amount of experimental information on cell morphology. A comprehensive review of the early literature was attempted by Kuhlmann-Wilsdorf^[76] and by Raj and Pharr.^[77] The description of dislocation cell morphology in connection with materials processing and resultant properties continues to be an area of active research.^[78,79]

Scanning electron microscopy does not afford sufficient resolution to image single dislocations or even groups of dislocations other than as indicated by the presence of concomitant surface inhomogeneities. However, for materials with cell diameters larger than the EBSD information

volume it is possible to image the location of dislocation cell walls in the SEM by the backscatter diffraction technique. This is made possible by the fact that coherent scattering of the diffracted beam is necessarily within a single crystal in order for well-defined Kikuchi lines to be observed. When diffraction occurs simultaneously from crystallites differing even slightly in orientation, destructive interference occurs and the sharpness of the diffraction pattern is decreased. Isabell and Dravid^[80] recently discussed this phenomenon in connection with polycrystalline Ni as observed in a cold field emission gun SEM. This measure of image diffuseness is quantified in an image quality (IQ) parameter. The image quality is determined by summing the difference in the values of the detected peaks in the Hough transform of the diffraction pattern from the background signal. Therefore, the parameter is a function of crystallite lattice orientation as well as various camera parameters. Within any given crystallite, however, the IQ parameter offers a good measure of crystal lattice integrity.

Pure Al (99.99%) was cold rolled to 80% deformation. Electron transparent specimens were prepared from the cross-section of the plate. Cell orientations were measured in the TEM using an enhanced variation of the technique described by Baggethun.^[81] The foils were subsequently analyzed in the SEM by orientation imaging.

Experiments and Results

Figure 28 shows a bright field TEM image of the region analyzed indicating a well-defined cell structure. The nominal orientation of the grain from where the image was taken is (211) with respect to the sample surface normal orientation. The bright field image was manually divided into individual cells and the orientation of various cells was measured using Kikuchi patterns. Figure 29 contains the individual cell interpretation of the bright field image and Fig. 30 contains an orientation image map of the cells

Fig. 28 Bright field image of the region analyzed by TEM

Fig. 29 Manually derived skeleton structure of the dislocation cells. The micron bar is 2 μm

Fig. 30 Orientation image showing orientations as measured from the TEM

for which an orientation was measured. The inset unit triangle in Fig. 30 contains an orientation color key for the colored map. The orientations shown are those with respect to the specimen normal direction. The data were analyzed for average cell size and for the misorientation angle distribution between neighboring dislocation cells. The cell size distribution and the mis-orientation angle histogram are given in Figs. 31 and 32, respectively. The average cell diameter using the assumption of equiaxed cells was 0.96 μm . The average dimension in the elongated direction was about 1.3 and 0.67 μm in the transverse direction as measured from the bright field image.

The same region was analyzed in the SEM by the orientation imaging technique. Figure 33 contains an image

Fig. 31 Dislocation cell size distribution as measured from the SEM and the TEM

Fig. 32 Misorientation angle histogram for dislocation cells as measured from the TEM and SEM

Fig. 34 Image quality map showing dislocation cell structure

quality map, a secondary electron map, and an orientation image of the entire region surrounding the hole in the TEM foil. All images are computer generated from signal obtained during the EBSD scan. A second orientation image was measured from the (211) grain in the same region as that analyzed in the TEM. The field of view imaged in the TEM is a fraction of that seen in the SEM, and the images are rotated with respect to each other, so the regions analyzed are not readily comparable. An image quality map of this structure is shown as Fig. 34. The dislocation cell morphology is apparent even though the misorientation angles between neighboring cells is typically less than 5°.

Figure 35 contains an orientation image with cell boundaries superimposed for all cells with misorientations greater than 1°. The average cell size (assuming equiaxed cells) as measured from the EBSD scan in the SEM was 1.03 μm. This compares favorably with the value of 0.96 μm measured in the TEM. The cell size distribution and misorientation angle histogram for this region as determined from the orientation imaging technique are included above in Fig. 31 and 32.

The cell size distribution is skewed toward smaller cells as measured in the TEM and leans toward larger cells as

Fig. 33 Secondary electron map (left), image quality map (center), and orientation map (right) generated from data obtained during an OIM scan. The color key for the orientation map is that shown in Fig. 30

Fig. 35 Orientation image of the dislocation cell structure. The color key is that shown in Fig. 30

measured by the SEM. These differences are small, however, and may be explained by the fact that the SEM measurements covered a significantly larger region than those from the TEM so the statistical distributions will likely differ somewhat. The differences observed in the misorientation angle distribution are also minor, but show a propensity for the SEM measurements to include more very low angle grain boundaries. This is attributable to the fact that the accuracy in relative orientation measurement by EBSD is on the order of 0.5° and some artificial boundaries on this order of magnitude may be introduced.

Discussion

From the evidence presented in the previous section it is apparent that dislocation cell structure for pure aluminum can be imaged in the SEM. It is not unreasonable to extend the result to claim that cell structure can be imaged in the SEM for any cell forming material that contains a stable cell structure larger than the resolution of the EBSD information volume.

Previous work has shown that in some instances, dislocation cell structure is a strong function of crystallite lattice orientation.^[82] If measurements of dislocation cell morphology are to be used in relating structural variables to material behavior, the dependence of cell morphology upon crystallite lattice orientation must be determined.

This requires a large number of measurements for statistically reliable information to be produced. To complicate matters further, grain interactions are known to play an important role in determining cell structure evolution,^[82] so the two-point orientation correlation function should also be simultaneously measured. Although it is feasible to implement fully automated orientation measurements in the TEM (Weiland and Field 1994), it is unrealistic to assume that such a quantity of information can be obtained by TEM techniques.

Proper quantification of dislocation cell morphology must include the anisotropy of dislocation cell shape, the clustering or banding of cells, and its dependence upon crystallite lattice orientation. One measure that can satisfy each of these objectives is that of a dislocation cell wall surface area per unit volume parameter that includes all of the appropriate dependencies. One could envision a measure described as:

$$S_v \equiv S_v(\mathbf{n}, g, \mathbf{r}, g') \quad (11)$$

where S_v is the stereological measure of cell wall surface per unit volume with functional dependence upon cell wall orientation, $\mathbf{n}$, lattice orientation, g , and neighboring lattice orientation g' which lies at a position $\mathbf{r}$ from g .

An alternate approach is to develop a cell shape and orientation distribution function which could also have functional dependence upon the two-point orientation correlation.^[83] This function may be written in two-dimensions as:

$$\xi \equiv \xi(a, b, \Phi, g, r, g') \quad (12)$$

where a and b are the major and minor axis dimensions of the cell, and Φ is the orientation of the major axis normal with respect to a reference axis. The extension of the function to three-dimensional space is straightforward and is accomplished by adding a third axis and an additional angle describing the orientation in vector space of the major axis. Correlation of cell shapes may be described by a two-point function, $h_2(\xi, \mathbf{t}, \xi')$, where $\mathbf{t}$ is a vector between cells of various shapes. The practical measurement of such a correlation function is still beyond reach as the function lies in a 14-dimensional space that is prohibitive in relation to experimental and computational techniques. Functions with reduced dimensionality or fixed parameters are currently tractable, however, and may be reasonably employed in the investigation of material microstructure.

Extracting the two-dimensional cell shape distribution function is a straightforward exercise from the EBSD data. Figure 36 contains a graphical presentation of the function (Equation 12 without crystallite lattice orientation dependence) as measured from the image seen in Figs. 34 and 35. The primary peaks in the function are at positions of small, nearly equiaxed cells, and at an angle 160° with the ratio of the major to minor axis dimensions at about $1.4 \mu\text{m}$ to $0.7 \mu\text{m}$.

There has been some discussion as to the actual character of dislocation cell networks from a three-dimensional perspective as these measurements are not possible from thin TEM foils. One advantage of the SEM approach is that a three-dimensional description of the dislocation cell structure could be measured directly using parallel serial sectioning techniques. Careful and repeated removal of a small layer of material from the specimen surface by controlled polishing or etching techniques has been used to measure particle distributions in opaque materials.^[84] Such a sectioning technique combined with orientation imaging could feasibly lead to direct measurement of the three-dimensional character of dislocation cell morphology.

Conclusions

This work on cold rolled pure Al plate material has clearly established the feasibility of measuring dislocation cell morphology in the SEM. The data of cell structure obtained by SEM/EBSD imaging differ from that derived from TEM techniques in a number of ways. First, the sharp Kikuchi lines in the TEM lend to a better angular resolution for measuring lattice orientation. In addition, the orientation and thickness of the cell walls can be extracted directly from TEM images while the SEM technique will give no information on cell wall thickness, and yields orientation information only through serial sectioning. Finally, while the spatial resolution of the EBSD technique is getting increasingly finer with each generation of SEM, the TEM has an advantage in spatial resolution. Information from materials with nano-scale dislocation cell sizes can be obtained only from high resolution TEM imaging.

There are several advantages to performing the analysis by SEM techniques where possible. Specimen preparation

is reduced to standard metallographic techniques thus saving considerable effort in comparison with the preparation of TEM foils. The large regions that can be imaged in the SEM allow for statistically reliable functions to be obtained, including the crystallite orientation correlation function. As discussed in the previous section, serial sectioning techniques may allow the direct measurement of the three-dimensional cell morphology that has previously been intractable.

APPLICATIONS TO GRAIN BOUNDARY NETWORKS

Grain boundaries, whose geometry can be described by the coincident site lattice (CSL) model^[85] and triple lines or junctions, are known to exert significant influence on mechanical and physical materials properties. Therefore, in principle, it should be possible to tailor properties for specific applications by exercising control over the population of grain boundary types in the microstructure. This was termed “grain boundary design and control” by Watanabe^[86] but now has evolved to the concept of “grain boundary engineering.” Recent demonstrations of the effect of boundary character and crystallography and the grain boundary character distribution (GBCD) include materials phenomena such as intergranular corrosion and cracking,^[87–93] creep behavior and cavitation characteristics,^[94–97] fracture toughness and plasticity,^[98,99] cold work embrittlement,^[100] and weldability.^[101,102]

Efforts to engineer the microstructure have primarily concentrated on changing the misorientation distribution function (MDF) or to increase the fraction of boundaries that exhibit specific disorientations characterized by the CSL model, or the so-called “special” boundaries by

Fig. 36 Dislocation cell morphology distribution for the orientation imaging data seen in Fig. 35

thermomechanical means^[103] or by other materials processing routes such as solidification or thin film deposition. However, a clear correlation between properties of the so-called “optimized” material and connectivity of grain boundaries is only emerging now; though conclusions to this effect have been drawn based on the increased proportion of special boundaries in the microstructure.

Advances in the engineering of grain boundaries in materials have been facilitated in recent years by the commercialization of automated EBSD techniques. This technique has largely superseded other experimental techniques, such as TEM and electron channeling in the SEM, for the determination of the GBCD due to the relatively straightforward specimen preparation and the large number of orientation measurements attainable in a relatively short period of time. It is easily recognized that the orientation mapping using EBSD data provides categorization of the individual boundaries, and this has been addressed earlier in the chapter. This is achieved by extracting the axis/angle character of the boundary using the simple geometric construction of the CSL model and then categorizing the boundaries as either special or random. The commercially available software for analysis of the EBSD data, however, is not particularly suited for this purpose because a boundary is only defined as the misorientation between adjacent data points. A string of such pairs of data points defines the grain boundary in the standard metallurgical sense of the word. Hence, the GBCD derived in this fashion is related to the spectrum of boundaries in terms of their length fraction, or rather the total length of all segments with a particular specification based on the CSL model. But it is well understood that percolative mechanisms that are responsible for intergranular failure phenomena are dependent on the frequency of boundary types rather than their length fraction. (The length fraction, however, may be a better descriptor for other properties.) In the following, data analysis useful to the area of grain boundary engineering will be described.

Categorization of Boundaries

As has been described earlier in the chapter, the experimental set-up automatically acquires and processes EBSPs for determination of local orientations, misorientations, and micro-texture. Thus, the three Euler angles that describe the orientation are recorded along with coordinates describing the position at spatially specific points in planar sections of the microstructure. Further, maps can be generated by plotting the crystal orientation onto a color or grayscale and shading each point on the grid according to some aspect of the crystal orientation. Alternatively, misorientations between points can be indicated by drawing boundaries that are color-coded by type of boundary, as, for example, special or random.

Thermomechanically processed samples of Inconel 600 and OFE-Cu were observed in a Hitachi S2700 SEM

with an automated EBSD attachment (OIM™, TSL, Inc., Draper, UT). The scans were carried out on a hexagonal grid, with each orientation point being represented as a hexagonal cell, using step sizes on the order of 1 to 5 μm over areas approximately 4×10 to $5 \times 10 \mu\text{m}^2$ in dimensions.

Maps of each region were produced with either image quality (IQ) or confidence index (CI) as a function of position and overlaid with boundaries in the range of 2° to 15° (low-angle) and 15° to 180° (high-angle). The disorientation was calculated for each high-angle boundary based on a particular rotation axis, and a comparison with the tables produced by Adams et al.^[104] showed which boundaries could be classified as special ($\Sigma \leq 29$) or random ($\Sigma > 29$). Since it is recognized that grain boundaries rarely have the exact disorientation, the Brandon criterion^[105] was applied for the appropriate tolerance from the exact CSL description. By counting the boundary types at each triple junction, we can categorize the grain boundary spectrum by their frequency.

A comparison of the GBCD obtained using length and number fractions is shown in Fig. 37 for the case of sequentially thermomechanically processed Inconel 600.^[106] From this analysis, it is clear that while similar trends in the GBCD are observed with increasing process cycles, the GBCD is marginally higher when special fraction is considered in terms of the total length of boundaries rather than by frequency. However, the fraction of $\Sigma 3$ boundaries is as high as 45 to 55% by length as compared to 25 to 32% when the measurement is by number fraction. This is a clear indication of a lower energy state being achieved by an increase in the length of low-energy $\Sigma 3$ boundaries at the expense of relatively higher energy boundaries rather than an increase in their relative number fraction in the microstructure. It is interesting to note in this context that the fraction of $\Sigma 9$ and $\Sigma 27$ boundaries increases considerably when measured by frequency. This is consistent with the suggestion^[107] that correlations associated with S9 and S27 boundaries occur as a necessity of geometrical considerations during the combination of two $\Sigma 3^n$ boundaries, such as the $\Sigma 3 + \Sigma 3 = \Sigma 9$ reaction, and not because of a reduction in total energy of the grain boundary network. A comparison between the two ways of representing the GBCD also illustrates the importance of $\Sigma 3^n$ variants, such as $\Sigma 9$ and $\Sigma 27$, for grain boundary engineering of low stacking fault energy FCC materials.

Typing of Triple Junctions

Modifications in the GBCD are a necessary, but not sufficient, condition to impact properties such as fracture characteristics that are primarily dependent on the spatial distribution and interconnectivity of the boundaries prone to crack propagation. While the increase in the fraction of special boundaries is desirable for improvements in certain materials properties, the benefits of such an increase should also be considered in the context of the triple

Fig. 37 Comparison of grain boundary character distribution by length and number fraction

junctions that comprise the boundary network. Hence, it becomes necessary to evaluate how even a single boundary or annealing twin can affect the crystallography of the neighboring interfaces in a reference tetrakaidekahedral crystal. It is quite apparent that the polycrystalline ensemble cannot be treated as a collection of isolated bicrystals or tricrystals since the twin boundaries exert an influence on the grain boundary network beyond their nearest neighbors. In an ideal case, it was suggested^[107] that the space filling operation could be carried out in the manner of the twin-limited microstructure. In a modification to this, Miyazawa et al.^[108] suggested that a three-dimensional polycrystal could be entirely composed of grains that adopt the shape of truncated octahedron with only $\Sigma 3$ and $\Sigma 9$ boundaries, or only $\Sigma 9$ boundaries, or $\Sigma 3$, $\Sigma 5$, and $\Sigma 15$ boundaries, or only $\Sigma 25$ boundaries. This data can also be obtained from an extension of the analysis used for boundary categorization.

As mentioned earlier, the misorientation maps are acquired on hexagonal grid points. Thus, each orientation point can be represented as a hexagonal Voronoi cell and the neighboring hexagons meet at triple nodes. This geometry is ideal for identifying triple junctions in the microstructure, i.e., the intersection of three hexagons. As is obvious from this discussion, the geometry of quadruple or other higher order nodes are not considered. Plots were produced identifying the location of low-confidence-index orientation points as a function of position and overlaid with boundaries. Boundaries with $\Sigma \leq 29$ were considered to be special while boundaries with $\Sigma > 29$ were considered random.^[109] The data was then surveyed to identify the location of triple junctions in the data set. A triple junction was identified as a triple node in the hexagonal array where three boundaries intersect. The triple points were

characterized after Fortier et al.^[110] and parsed among four groups: three special boundaries (S-S-S or 3-CSL), two special boundaries and one random boundary (S-S-R or 2-CSL), one special and two random boundaries (S-R-R or 1-CSL), and three random boundaries (R-R-R or 0-CSL). An example of such analyses is shown in Fig. 38. The random grain boundaries are denoted by the thick black lines whereas the thin lines with the lighter grayscale shading are the special boundaries. The different categories of triple points are marked as differently colored triangles with the 3-CSL junctions shaded in red, 2-CSL in light blue, 1-CSL in green, and 0-CSL in dark blue.

Fig. 38 Typing of triple junctions over the EBSD map in Inconel 600

Data gathered from thermo mechanically processed of-Cu and a Ni-base alloy (Inconel 600) is represented in Fig. 39 as a function of the frequency of special boundaries in the microstructure. It is readily seen that extraction of triple junction distributions is only possible when the number fraction of special boundaries has been determined from the analysis of the previous section. The triple junction distribution shows a dramatic drop in the 0-CSL fraction from the value for the starting material, eventually leveling off to about 5% of the total number of the triple junctions. An increase, and then a slight decrease, in the fraction of 1-CSL junctions is commonly seen within the bounds of the special fraction observed in the above-mentioned materials. This distribution dominates the microstructure when the special fraction is in the range of 50%. At this point, the 2-CSL distribution also plateaus at about 20%, though surprisingly, the variation in the 2-CSL distribution is quite narrow in this range of special fractions. The proportion of 3-CSL junctions remains negligible until the GBCD attains a value of about 30%, and then shows a very significant increase beyond this level with a maximum value of about 40% for the experimentally determined GBCD presented here. An increase in the S_3 fraction promotes the formation of triple junctions comprising of 3-CSL boundaries, which also indicates that clustering of multiple twinning events promotes the formation of other $\Sigma 3^n$ variants, like $\Sigma 9$ and $\Sigma 27$, in the microstructure.

The triple junction distributions derived experimentally do not compare favorably with probability calculations or analytically derived distributions from Fortier et al.,^[110] as shown in Fig. 39. Reasonable agreement is observed with respect to the trend and absolute distribution of 3-CSL and 0-CSL junctions with proportion of special boundaries. This finding is not surprising since these two distributions are not dependent on spatial correlations of the constituent boundaries with the nearest neighbors; hence, the experimental data should match probability functions even where the combination rule for triple junctions ($\Sigma x \cdot \Sigma y = \Sigma xy$ or $\Sigma x/y$),^[108] that reflects lattice correlations is not enforced.

The results from this study (Fig. 39), however, show significant departure with the simulations of Fortier et al.^[110] when the 2-CSL and 1-CSL distributions are considered. The analytical probability calculations are symmetric for these two distributions with the proportion of 2-CSL junctions increasing sharply to a maximum at about 66% special fraction, but this is not observed experimentally. Moreover, the absolute values obtained here are much lower in comparison. Significantly, the experimentally measured distribution of 1-CSL junctions is higher than the predicted values from simulations or analytical calculations when the special fraction increases beyond 50%. These observations emphasize the point that the 1- and 2-CSL distributions are strongly correlated with the overall distribution of grain boundaries in a polycrystalline

Fig. 39 Triple junction distribution in ofe-Cu and Inconel 600 as a function of special fraction

ensemble, and this aspect does not appear to have been captured in the probability calculations.^[110]

To confirm this point, computer simulations of the microstructure were conducted assuming grains to be of hexagonal morphology but without enforcing the combination rule suggested by Miyazawa et al.^[108] for the connectivity of boundaries at triple junctions. For these calculations, an infinite pool of boundaries was assumed with a modified GBCD. The modification in the distribution was to assume only $\Sigma 3^n$ (where n is an integer from 0 to 3) CSL boundaries and the rest as random, thus giving a slight underestimation of the GBCD. These simulations emulated the distributions obtained by Fortier et al.^[110] quite remarkably, as shown in Fig. 40. These results, however, were not in agreement with the experimental observations, which have also been plotted for comparison in Fig. 40, thus predicting that the analytical solution does not contain information on the connectivity of the individual elements of the grain boundary network.

Fig. 40 Comparison of experimentally determined triple junction distributions with probability analysis of Fortier et al.^[110] Source: With permission.

However, the distributions from the simulated microstructures (dashed heavy lines in Fig. 41) are in reasonable agreement with the experimental data when the spatial correlation at triple junctions is strictly enforced, i.e., the combination rule ($\Sigma x \cdot \Sigma y = \Sigma xy$ or $\Sigma x/y$) for the CSL designations of grain boundaries is applied. The simulations of the triple junction distribution based on the GBCD produced via multiple twinning events^[111] are in close agreement with the experimental observations, marked by the closed symbols in Fig. 41. It appears that enforcing the combination rule at an isolated triple junction is sufficient to explain the triple junction distribution obtained experimentally, particularly for the case of GBCD where there is a concomitant pseudo-randomization of texture. A small fraction of the sample of 1,000 triple junctions considered in the simulations failed to meet the combination rule, but this number is significantly less than the failures reported for strongly textured materials.^[110] The minor discrepancy between the simulated and experimental results probably stems from not considering the full spectrum of CSL boundaries and the fact that the connectivity of triple junctions is not explored in a three-dimensional simulated microstructure.

Extraction of the Random Boundary Network

An important aspect of assessing the optimization of the microstructure is to correlate microstructural parameters like the grain boundary character and triple junction distributions with the connectivity of grain boundary networks that are susceptible to failure. Wells et al.,^[112] on the basis of a bond percolation formulation, suggested an appropriate function that would describe when the assembly of grain boundaries in the microstructure attained a critical value of active segments. On the basis

Fig. 41 Comparison of experimentally determined triple junction distributions with the results of the microstructural reconstruction using the rules of Miyazawa et al.^[108]
Source: With permission.

of these simulations, they predicted that the minimum fraction of random boundaries in a three-dimensional lattice structure that would lead to the formation of a one-dimensional continuous linear chain was 0.23. However, when a planar section was considered, based on an approximation of the two-dimensional microstructure to a honeycomb network, this boundary fraction reached a value of approximately 0.65. This suggests that the probability of cracks propagating through the microstructure would be considerably reduced as the special fraction increases beyond 0.35.

This type of probabilistic analysis was further extended in the work of Palumbo et al.^[90] to assess the crack resistance of a microstructure. This model was based on the fraction of crack-resistant grain boundaries, or the GBCD, but did not include consideration of the spatial arrangement of these special boundaries. The approach of Gertsman and Tangri^[113] further combined both the percolation and Markovian description in a probabilistic methodology and were able to predict percolation thresholds using both the grain boundary character and triple junction distributions. Interestingly, in all the above studies where a two-dimensional microstructure was assumed the threshold value of susceptible boundaries for crack propagation is about 0.65, which agrees closely with the value obtained from the bond-percolation calculation.

The probabilistic nature of these approaches, however, does not fully incorporate the possible correlations that exist in a grain boundary network. This suggests that the methodology for optimization of the microstructural topology cannot solely be based on improvements in the GBCD, although it is a necessary parameter. Moreover, the path length that was assumed in the analysis may be an overestimation of the critical length in the materials phenomenon in consideration. Another caveat is that not every special boundary can be characterized as having the same degree of resistance to crack propagation. The interpretation of such data should also include information on the other degrees of freedom that the boundary possesses such as the grain boundary habit plane.

It was mentioned earlier that it would appear as if the GBCD in these materials had not been optimized, as they did not approach the theoretical maximum of the twin-limited microstructure. As a first-order approximation of the spatial correlation of boundaries in the microstructure we can examine the distribution of triple junctions and consider them the unit entities active in intergranular failure. In order to assess the resistance of the microstructure, however, we need to consider the distribution of only those triple junctions that comprise of at least one boundary that is susceptible to cracking. Therefore, the 3-CSL triple junctions can be taken out of consideration, as they are inactive entities in the process of arresting advancing cracks based on the assumption that the failure front would never approach them. For a continuous percolative path

Fig. 42 EBSD orientation maps with the special boundaries in color faded to the background and the random boundary networks highlighted in black

in the microstructure at least 65% of the remaining triple junctions should pose no barrier to the advancing crack front. Thus, in an inverse analogy to this threshold we can predict that percolative paths in the microstructure will be broken if the following inequality holds:

$$\frac{f_{2\text{CSL}}}{f_{(1-3\text{CSL})}} \geq 0.35 \quad (13)$$

where $f_{2\text{CSL}}$ refers to the fraction of triple junctions that have two special boundaries and are thus able to arrest intergranular cracks and $f_{(1-3\text{CSL})}$ is the fraction of triple junctions that are active unit entities in the microstructure.^[106]

Hence, the break-up of continuous percolative paths in the microstructure requires the fraction of triple junction comprised of 3 and 2 special boundaries to be enhanced by the thermomechanical processing such that the above inequality is satisfied. The data presented in Figs. 39–41 shows that the 2-CSL junction distribution remains almost constant during the multi-cycle treatment, but there is a dramatic increase in the 3-CSL junction distribution and the inequality in Eq. 13 is close to being satisfied. An extrapolation of this data shows that the special fraction at the percolation threshold when considering triple junctions rather than boundaries as active segments is significantly higher. This suggests that the process of reducing the connectivity of random boundaries to shorter path lengths is well underway in the experiments presented here, but the percolative processes have not been completely eliminated.

The break-up of the random boundary network as a function of sequential processing conditions could also be visually examined from the misorientation maps shown in Fig. 42 for the case of Inconel 600. The first map (Fig. 42a) shows the microstructure in the material processed through one cycle of strain and annealing. Only the random boundary network is shown with all the

special boundaries that were present in the original map faded to the background. It was quite apparent that the connectivity of the random boundaries extended through the imaging area. The next two maps (Figs. 42b,c) show the tremendous improvement in the break-up of the random boundary network after the subsequent processing cycles (3 and 4, respectively) with a sharp decrease in the relative frequency of random boundaries beyond process cycle 1. This is the regime where the 3-CSL junction distribution shows a sharp increase compared with the as-received material. Also noteworthy is that the break-up in the connectivity of the random boundaries continues even though the GBCD increases only marginally during the later stages of the processing.

CHRONOLOGY OF EBSD DEVELOPMENT

The following is a collection of papers and documented events in the development of EBSD and the automated

techniques that include mapping the crystallographic morphology of polycrystalline structures. The list is

adapted from a compilation of S.I. Wright of TexSEM Laboratories.

First reported observation of High-Angle Kikuchi Patterns (termed Electron Backscatter Diffraction Patterns by later authors).

Use of EBSPs for determination of lattice orientation. Introduction into the SEM.

Introduction of a video camera to view EBSD images.

On-line indexing of EBSD patterns. The user is required to identify the position (by point-and-click) and (hkl) of at least two zone axes in a pattern.

Use of bands instead of zone axes to determine the orientation. The advantage here is that an operator is not required to identify the crystallographic parameters of the bands but to simply digitize them. These ideas were first applied to Electron Channeling patterns but later extended to EBSPs.

Schmidt, N.-H. and Olesen, N.Ø. Computer-aided determination of crystal-lattice orientation from electron-channeling patterns in the SEM, *Canadian Mineralogist*, 27, 15–22, 1989.

In order to automate orientation determination from EBSPs some form of image analysis for either detecting the zone axes or the diffraction bands in the images was

needed. The following lists the sequence of developments in this area.

The first attempt to automatically determine the lattice orientation from an EBSD image was done by trying to detect zone axes in the pattern.

The first attempt to detect the bands instead of the zones was done by segmenting EBSD patterns into smaller binary images. Lines were detected in these smaller images and then linked together with lines detected in other segments to form the detected bands.

Another attempt to find the bands using gradients of the EBSD images via the Burns algorithm was successfully employed.

The application of the Hough Transform for band detection. This is the most widely used method today.

Russ, J.C., Bright, D.S. and Hare, T.M. Application of the Hough transform to electron diffraction patterns, *Journal of Computer-Assisted Microscopy*, 1, 3–37, 1989.

The next step was to automate the system so that repeated measurements of orientations could be made without any operator intervention.

Orientation Mapping

One of the more eye-catching uses of the automated systems is to create color-coded orientation maps. However,

The first completely automated scan was performed using the Burns method. 4167 points were measured. The scan was performed by translating the sample under a stationary electron beam.

The first published description of the fully automated system.

Current systems tend to generally perform scans by controlling the electron beam instead of translating sample stages.

Confidence index parameter devised. This parameter allows an operator to distinguish between data that is correctly indexed from data that may be suspect (generally due to weaker patterns).

Results were presented by S. I. Wright as part of an unpublished talk entitled "Local volume fraction fluctuations and clustering in polycrystals" at the *Microscale Textures of Materials Symposium at Materials Week '91*, Cincinnati, Ohio, October 1991.

the ideas for such maps have been in existence for some time. Dark field imaging in the TEM, polarized light microscopy, and backscatter imaging are all forms of orientation mapping. Thus, the idea of forming microstructural

images based on crystallographic orientation have existed for some time. However, such methods are generally not very quantitative. The following are some quantitative methods.

The mapping of orientation onto a microstructure was done by "hatching" and coloring a pole figure using different patterns at different locations in the pole figure and then using the same patterns on a microstructure traced from micrographs.

The stereographic unit triangle (inverse pole figure) was used in a continuous color coding scheme where red is assigned to the (110) direction, blue to (111), and yellow to (100) and then points lying between these three corners of the stereographic triangle are combinations of these three colors. This color coding is then used to shade grains in digitized maps of the microstructure according to their orientation.

A similar continuous color coding scheme was devised by assigning red, green, and blue to the three axes of Rodrigues–Frank space and then coloring digitized microstructures accordingly.

The first reconstruction of a microstructure from automated orientation measurements was performed by drawing line segments between neighboring points in a hexagonal measurement grid wherever the misorientation between a pair of neighboring points exceeded some user defined value. The first color coding of such maps was done by selecting a few ideal components of the texture and then shading measurement points according to their distance in orientation space from these ideal orientations.

Polarized light has long been used to show differences in orientation by color contrast. However, new methods quantifying such images have been developed..

Phase ID

Besides using EBSD technology for determination of lattice orientation there has been much interest recently in the use of EBSD technology for identifying crystal phase. The following list some of the key works done in this area.

Manual use of EBSD images for phase identification.

The groundwork for an automated system for phase identification based on both interplanar angles and d-spacings was published. An automated system is under development.

The first commercial system with built in tools for differentiating phases based on a best fit approach according to indexing of EBSPs was released. This system also enables chemical and orientation data to be measured simultaneously using an integrated OIM/EDS system.

of the characterization issues that had been previously been tedious or impossible to address with existing technology. A recent book on EBSD addresses many of the applications to aluminum and other metals and crystalline materials.^[16] The following list is by no means a complete collection of all papers on applications of aluminum processing and metallurgy that have been addressed using EBSD technology, nor is there a complete set of references for any given topic shown below. The following is merely given as an indication of the wide variety of applications to which EBSD is applied in aluminum research, and as an aid to the reader to begin a literature search on EBSD applications to aluminum processing in any of the areas listed.

Applications of EBSD in Aluminum Research

Academic and industrial researchers have long recognized the need for more complete microstructural characterization in addressing issues relevant to structural optimization during aluminum processing. EBSD techniques obtain statistically reliable information on many

Abstract

Aluminum alloys are the subject of increasing interest in the automotive industry, as well as the aircraft industry, aiming to reduce the weight of components and also allowing a profit in term of energy saving. In assembly process, riveting has been widely used in the aircraft industry, whereas welding seems to be available in the car industry in the case of aluminum alloys. Nevertheless, conventional fusion welding can generate defects, such as gas porosity, oxide inclusions, solidification cracking (hot tearing), reduced strength in both the weld, and heat-affected zone (HAZ), which could limit its development. Electron beam welding (EBW) has unique advantages over other traditional fusion welding methods due to high energy density, deep penetration, large depth-to-width ratio, and small HAZ. EBW has been developed for many years and is being increasingly implemented in various industrial applications. In many cases, it has proven to be an efficient method for joining difficult to weld materials. One of the major problems associated with the EBW is how to select a proper combination of the process parameters because improper selection of these parameters causes defects in the weld joint, which could seriously influence the weld mechanical properties. This work introduces an overview of the EBW process, its parameters, process simulation, process optimization, and finally characterization of the electron beam weld joint of 2219 aluminum alloy.

Keywords: Aluminum alloys welding; Electron beam welding; Grey relation analysis; Strength and hardness of welded joints; Taguchi method; Welding parameters optimization; Weld joint characterization.

INTRODUCTION

Aluminum is the first non-ferrous metal used in industry due to its distinguished chemical, physical, and mechanical properties. It represents an important category of technological materials. Aluminum and its alloys are characterized by their high strength-to-weight ratio; some of its alloys have strengths greater than that of structural steel, besides other appropriate properties, e.g., desirable appearance, nonmagnetic, high corrosion resistance, and high electrical and thermal conductivities, and can easily be fabricated into any form and readily accepts a wide variety of surface finishes. Aluminum and its alloys are used extensively in chemical plants and food processing equipment. Aluminum cobber alloys with high strength are used extensively in the aircraft industry. Special alloys are also used for automobile applications. However, there have been challenging weldability problems for aluminum alloys to overcome.^[1,2]

Some of the chemical and physical properties of aluminum need to be understood before selecting the appropriate joining process. The high affinity of aluminum to

oxidation, its oxide characteristic, the solubility of hydrogen in molten aluminum, and the wide range of mechanical properties and melting temperatures that result from alloying with other metals should be well investigated before using welding as a joining process for aluminum and its alloys as the preceding properties severely affect the properties of the weld joint.

Fusion welding is one of the most widely used methods for the joining aluminum and its alloys; however, it has many drawbacks, namely gas porosity, oxide inclusions, solidification cracking, reduced strength in the fusion zone and heat-affected zone (HAZ), lack of fusion, reduced corrosion resistance, and reduced electrical resistance.^[3] There are several other types of joining methods that are also used, and may often be associated with fewer difficulties for producing aluminum joints. These are solid-state welding, brazing, soldering, adhesive bonding, and mechanical joining. Most of these techniques can eliminate the fusion problems because the base metals remain in the solid state during joining. Therefore, they are better than fusion welding in this respect.^[4] Nevertheless, the service conditions may make particular

processes inapplicable, as for high-temperature applications, soldering and adhesive bonding cannot be candidates; while for leak-tight joints, mechanical joining is not acceptable. Furthermore, the required joint geometry can make friction welding difficult to apply. Diffusion welding often provides superior technical benefits for joining small metal parts, but the process is rather time-consuming.

Although electron beam welding (EBW) is a fusion welding process and may still encounter the preceding problems, it may, however, reduce or overcome the problems to a certain extent and consequently produces satisfactory joints. EBW is distinguished by extreme power density associated with the electron beam (EB) and the ability to work in a vacuum environment. This makes it possible to use the process for joining metals that not only have high melting points but also those that are extremely reactive when hot or molten. Therefore, these advantages make EBW widely used in the aerospace industry for welding aluminum alloy parts.^[5]

ELECTRON BEAM WELDING PROCESS

EBW is a method of joining materials in a vacuum using a strongly focused beam of high-velocity electrons. This stream of electrons is accelerated to a speed equals 0.3–0.7 the speed of light. On impact of electrons with the workpiece, the kinetic energy of the electrons changes into heat resulting in a high power density of order of magnitude of 10^8 W/cm². This great power density is sufficient to vaporize a small amount of the workpiece of any known metal forming the so-called keyhole. This keyhole is surrounded by molten metal; consequently by moving this keyhole in a certain path, the material of the two parts around it melt and mixed together, and on cooling, the molten material resolidify forming the weld joint. The vacuum is necessary to prevent scattering of the electrons by collision with gas molecules.^[5–7]

Typically, an EBW system consists of an electron beam gun, power supply, vacuum system, and video control unit. These subsystems work together to generate the electron beam and to provide the optimum environment for the process.^[8]

The four functions of the electron beam gun are to generate free electrons, accelerate the electrons, control the flow of the electrons to the workpiece, and focus the electron beam at a certain location.^[5,9]

The power supply used in EBW systems provides source of electrical energy for heating the filament, accelerating the electrons, controlling the bias grid, focusing the beam, and operating the deflection coil. The controllable parameters for the power supply are the accelerating voltage and beam current. These parameters determine what kind of applications the particular system will be capable of performing.^[9,10]

Most EBW is performed in a welding chamber that has been pumped to a high vacuum. This is necessary to ensure optimum beam propagation and focusing. Because electrons have mass, they interact with air molecules, which results in beam dispersion and a large loss of energy. A secondary benefit of performing the EBW process in a vacuum environment is that the molten material in the weld joint undergoes a vacuum melting and refining process. These result in a high weld material purity and a favorable weld joint.^[9,10]

EBW systems are equipped with a computerized video control unit (VCU), the resulting picture is displayed by the monitor. The VCU operation principle is based on reception and decoding of the signal coming from the secondary electron sensor when the electron beam system is operated in the low current mode (0.5–1.0 mA). The VCU enables accurate aiming of the electron beam at the joint edges of the welded part and monitoring the welding process.^[11]

ELECTRON BEAM PROCESS PARAMETERS

The most important variables for producing the desired results in EBW are the accelerating voltage, beam current, beam power, traverse rate, sweep size, and beam spot size.^[4,10,12–14]

Increasing the accelerating voltage or beam current increases the penetration depth. The product of these two variables equals the overall beam power, which, in turn, determines the amount of material melted for a given welding traverse rate. Furthermore, as the accelerating voltage increases, the aspect ratio of the weld also increases. While, increasing the welding traverse rate and maintaining all other variables constant decreases the energy input per unit length, consequently the depth of penetration and the width of the weld bead decrease. The diameter of the electron beam on the workpiece is influenced by the gun design, beam current, focus current, and standoff distance. Most electron beam systems are capable of focusing the beam to diameters as small as 0.25 mm. Finally, with the various levels of vacuum available for performing EBW, the level of vacuum in which the welding is performed must be considered a variable. As pressure increases, welding penetration decreases and the width of the fusion zone increases.^[8,13,14] The need to carefully select and monitor these variables increases as the penetration depth increases. To meet this requirement, many of the electron beam welders currently being manufactured incorporate programmable controls to set and maintain the process parameters.^[15]

The process engineers also have interest in collecting information concerning EBW parameters, aiming to correlate between EBW parameters and the quality of weld. As an example, the work done by Zuhair et al.^[13] was to investigate the effect of EBW parameter on ultimate tensile

strength (UTS) of 1350 Al-alloy; they found that UTS increase with increasing beam current until the maximum value and then decrease with any increase of beam current. They also found that changing focal position from the middle of the workpiece leads to decrease penetration depth and so UTS decreases.

Mladenov et al.^[16] investigated the correlation between the process parameters such as weld depth, focusing parameter, and thermal efficiency of EBW of austenitic stainless steel. They reported that when the beam focusing value is varied, the weld depth decreases strongly. The values of the thermal efficiency are in the range of 0.33–0.48, and also reported that deep and narrow welds obtained by lower powers lead to the presence of bubbles situated usually at the middle of the weld depth.

Sazonov^[17] studied the various type of flaws arising in welded joints during EBW, and the factors causing these flaws. He reported that the instability of such EBW parameters as accelerating voltage, beam current, and focusing current lead to oscillations in the melting depth. The influence of the focusing coil is especially strong. For example, changing the focusing current value by 2% leads to a change in the melting depth by 50%. Therefore, during the development of welding equipment, engineers strive to stabilize these parameters.

Richarde et al.^[18] studied the influence of EBW parameters on HAZ micro-fissuring in INCOLOY 903, they reported that reduction in welding speed and an increase in beam current for a given heat input would minimize HAZ micro-fissuring in this alloy.

Shakeri et al.^[19] studied the effect of the working distance on the weld bead, they stated that the non-vacuum EBW process is not able to produce an impingement spot as small as that attainable with vacuum EBW and this is due to interactions between electrons in the beam with the ambient air molecules and this interactions increase as distance traveled into the atmosphere.

An attempt was made by Chi and Chao^[20] to evaluate electron beam weldments of AZ61A-F extruded plates; they reported that UTS of AZ61A alloy increases with increasing beam current and accelerating voltage, whereas it decreases with increasing welding speed.

Yilbas et al.^[21] investigated the mechanical and metallurgical properties of electron beam-welded austenitic 321 stainless steel tubes of different thickness. They observed that HAZ increased as the workpiece thickness increased, and transverse microcracks were present at the boundary of the molten and solid regions. They also observed that electron beam power is the most important parameter for maximum penetration.

Chao-Ting et al.^[12] analyzed the influences of EBW parameters on weldment strength and defect formation by linking Taguchi's method with the grey relational analysis. They reported that the oscillation beam contribution and focal position are primary parameters that have the most significant effect on AZ-series weldment strength.

Kim and Kawamura^[22] investigated the effects of beam irradiation position on mechanical and microstructural properties of Zr-based BMG/Ni joints. They reported that the electron beam irradiation position had a strong influence on the joint properties. When the electron beam was too far from the crystalline metal, no joining was achieved, and when the electron beam was too close to the crystalline metal, it led to crystallization in the weld.

EBW PROCESS MODELING

Modeling of EBW is a complex process, where this process is controlled by several parameters like beam current, voltage, etc. Unlike many other fusion welding methods that only heat the surface of the weld joint, the EBW heat source can provide the energy through the thickness of the workpiece via the keyhole. Thus, it is necessary to take the keyhole shape into consideration when an EBW thermal source model is established. Many analytical 2-D or 3-D models of the electron beam thermal source have been developed.

Ho^[23] proposed an analytical model to predict the shape and depth of transverse section of fusion zone during welding. His results revealed that a focused beam with small focal spot size and beam-convergence angle can induce a deep and narrow fusion zone, and the deepest penetration occurs when the focal spot is located at the position between the workpiece surface and the bottom of the fusion zone. The shapes of deep and shallow fusion zones approximate a cone with a spherical cap and a parabolic revolution, respectively. The shape of the fusion zone, calculated by this work, has the same tendency as the experimental observation when the focal location relative to workpiece surface is varied.

Luo et al.^[24] developed a mathematic model to simulate the power density distribution during EBW. The model results in the following important findings: first, the affecting radius of source model decreases progressively with the law of Gaussian function. Second, the power density varies gradually with the law of exponential function in depth direction.

Ching-Yen et al.^[25] proposed an analytical thermal model to predict the cavity temperature during EBW; in this model, the keyhole produced by an electron beam is assumed to be parabolic in shape, and the intensity of electron beam is supposed to be Gaussian profile. It was indicated that the analytical solution obtained by this model provides temperature distribution more consistent with the obtained experimental data.

EBW PROCESS OPTIMIZATION

Dey et al.^[26] utilized the regression analysis to correlate between the input parameters of EBW process of 5 mm thickness austenitic stainless steel plates and

the output weldment quality measures. The used input parameters are accelerating voltage, beam current, and welding speed, while the used output quality measures are the bead width, bead height, and penetration depth. Moreover, they used a generic algorithm to minimize the weldment area by minimizing the bead width and height and maximizing the penetration depth. The minimum values of the bead width and bead height were found to be equal to 0.22 and 1.58 mm, respectively. The maximum value of penetration depth was found to be equal to 5.02 mm. These optimum values were obtained at accelerating voltage of 60 kV, beam current of 8.78 mA, and welding speed of 759.9 mm/min. In another work, the same methodology was followed to minimize the weldment area of a 12 mm Al 1100 aluminum sheet welded by electron beam. They obtained a minimum area of 286 mm² corresponding to minimum bead width of 3.7 mm and maximum bead penetration of 10.5 mm. These optimal values were obtained at accelerating voltage of 80 kV, beam current of 50 mA, and welding speed of 1055.3 mm/min.^[27] The collected experimental data of Dey et al.^[26] were used and treated with another method by Bahrami et al.,^[28] where they considered the weld penetration shape factor, weld reinforcement form factor, area of penetration, area of reinforcement, bead cross sectional area, and dilution percentage as quality measures for the EBW process. They utilized regression analysis to draw four equations correlating the preceding responses to the EBW process parameters. After that they employed simulated annealing algorithm to find the optimum input parameters, which are accelerating voltage of 90 kV, beam current of 9 mA, and welding speed of 600 mm/min. Although these results are completely different than the results of Dey et al.,^[26] no explanations were given.

Tahuchi method with orthogonal array was used by Elseddig^[29] and Sobih et al.^[15] to design the experimental work used to investigate the EBW process of 5 mm thickness 2219 Aluminum alloy. The input parameters in this study were the sweep size, the beam current, the welding speed, and the focusing current, whereas the characteristics measures were yield strength, hardness, penetration depth, and bead width. The results of the experimental work were statistically analyzed with the Grey relation to obtain the optimal process parameters yield to maximum yield strength, hardness, and penetration depth; and minimum bead width. The output of this optimization process was summarized in Table 1. The obtained maximum yield strength represents 62% the strength of base metal and this result is better than that obtained by Koteswara et al.,^[30] who reported that the maximum yield strength of 2219 Al-alloys welded by gas tungsten arc welding is 204 MPa, which is only 52% of the yield strength of the base metal. This result was validated experimentally and the evaluation of the resulted weld joint was presented by Elseddig^[29] and Sobih et al.^[31]

Table 1 The output of the optimization process of Elseddig^[29] and Sobih et al.^[15]

Parameter	Value
Welding speed	600 mm/min
Beam current	18 mI
Sweep size	6
Focusing current	909 mI
Maximum yield strength	243 MPa
Maximum hardness	78.7 BHN
Maximum penetration depth	5 mm
Minimum bead width	3.51 mm

ELECTRON BEAM WELD JOINT CHARACTERIZATION

To characterize and evaluate electron beam weld joint of 2219 aluminum alloy, two pieces of 2219 aluminum alloy with dimensions of 50 × 60 × 5 mm were welded together using 60kW Seo TECH-60 electron beam machine. The specimens were welded using the optimal parameters obtained from previous study;^[15,29] these parameters are welding speed of 10 mm/s, beam current of 18 mA, focus current of 909 mA, and sweep size of six. These parameters lead to maximizing hardness, tensile strength and penetration depth, and minimizing bead width. After the two plates welded together, the specimens are sectioned in transverse direction to conduct tensile test, hardness test, and metallographic observations. Specimens for metallographic observation are suitably sectioned in transverse direction of the welding; the samples were then mechanically polished according to standard metallographic procedures and etched using Keller's reagent (95 mL water, 2.5 HNO₃, 1.5 mL HCL, and 1.0 mL HF) for 10–20 s. Because Keller's reagent contains HNO₃ and HF, which are extremely hazardous, great care is required to avoid contact with skin. After etching in Keller's reagent, a macrostructure of welded sample was observed by (SEMMA-202M) scanning electron microscopy (SEM) at magnification of 50×, and penetration depth and bead width were measured using optical microscope. The metallurgical observations (macrographs) were carried out by optical microscopy and SEM. X-ray diffraction (XRD) was utilized to determine the different phases that developed in the fusion zone microstructure and base metal. XRD was carried out by Xpert Pro machine with the following parameters: accelerating voltage = 40 kV, tube current = 20 mA, and diffraction patterns were obtained in the step 2θ mode in the range of 10°–140°.^[29,31]

General Characteristic of the Grain Structure in Weld Zones Structure

Generally, there are four zones within a fusion welding: the parent material (the unaffected base metal) followed by the lower temperature zone known as “overaging,” then

Fig. 1 Optical macrograph of weld zones of EBW joint^[29,31]

the higher temperature zone known as solution treated, and finally the fusion zone. Figure 1 shows an optical macrograph of weld zones for optimal sample; this macrograph reveals that the fusion zone is characterized by columnar dendritic at fusion line and equiaxed dendritic at weld centerline. Figure 2a shows the parent material's grain structure, where the microstructure of the parent material consists of elongated grain in the longitudinal direction, as a consequence of deformation introduced during rolling. In addition, SEM images, Fig. 2b, reveal that the grain and sub-grain were decorated with a fine dispersion of second-phase particles that are most likely Al_2Cu ; these precipitates are associated with age hardening developed from GPZs within the grain. This result is confirmed by XRD analysis.^[29,31]

(a)

Effect of Welding Condition on Solidification Mode

A macrostructure investigation was carried out on the optimal weld to understand the solidification characteristic of weld zone. A cross section of the weld is shown in Fig. 3; this macrograph illustrates the appearance of the weld zone and the solidification mode in the transverse plane, and how the solidification mode changes from columnar dendritic solidification at fusion line to equiaxed dendritic solidification at center of the weld. These solidification modes have been reported by a number of researchers for several different materials.^[32–34] The mode of solidification can be planar, cellular, columnar dendritic, or equiaxed dendritic. The particular type of solidification forms depending on the solidification condition and the material system involved. Low under cooling favors cell formation whereas high under cooling favors dendrite formation. At very high under cooling, nucleation will occur ahead of the solid/liquid interface resulting in equiaxed dendrites and grain refinement.^[29,31]

Effect of Welding Condition on HAZ Grain Structure

HAZ (Fig. 4), is a transition zone between the base material and the weld zone. The microstructure of the HAZ varies from the microstructure of typical Al 2xxx series (nearby the base material region) to the microstructure of the weld zone in the neighborhood of the FZ. The lower temperature zone near the unaffected base metal known as overaging is shown in Fig. 4a, which indicated that the precipitates grow to such a size that they lose coherency with the matrix. The higher temperature zone near the fusion zone known as solution-treated zone is shown in Fig. 4b. Thickening of grain boundaries were observed in this zone, which indicated that the precipitate particles are completely dissolved at high temperature and upon cooling some of these particles are precipitate at grain boundaries eliminating the effects of the age hardening.^[29,31]

(b)

Fig. 2 Microstructure of the parent material: (a) Optical micrograph and (b) SEM micrograph^[29,31]

Fig. 3 Optical macrograph showing plane view of the optimal weld^[29,31]

Effect of Welding Condition on Fusion Zone Grain Structure

Figures 5 and 6 illustrate SEM micrographs of the grain structures that are found in fusion zone. The images are taken from six positions and three positions at the fusion line, Fig. 5: 0.5 mm below the top of fusion line; at the center of fusion line; and 0.5 mm above the root of fusion line, the other three positions at the weld center line, Fig. 6: 0.5 mm below the top of weld; at the center of the weld; and 0.5 mm above of the root of weld. The microstructure at the fusion line for all positions, Fig. 5, revealed the columnar dendritic growing from each base metal grain (epitaxial

growth). Also, the grains at and along the fusion line were observed to be oriented toward the center of the weld without altering their existing crystallographic orientations, and this direction is perpendicular to pool boundary because this is the direction of the maximum temperature gradient and hence maximum heat extraction.^[29,31]

The microstructures at the center of the weld zone at three different positions (top, center, and the root of weld), Fig. 6, reveal that the weld center is characterized by different grain structure from top to root of weld. The region near the top surface of the weld at the weld center line, Fig. 6a, where the solidification rate is equal to welding speed, was characterized by equiaxed grains. However, the grain, in the center and root of the weld center, was characterized by columnar dendritic. The nature of solidification as well as welding speed contributes to the formation of the equiaxed grain in the centerline of aluminum alloys' weld. Because increasing welding speed as in the cases of EBW lead to increasing solidification rate.^[29,31]

Results of X-ray Diffraction

Figure 7 illustrates the XRD pattern obtained on the base metal. We can recognize a series of diffraction peaks with the different intensity corresponding to α phase and generated by the constructive interference on different crystallographic planes. The most intense among the peaks appeared at $2\theta^\circ = 37.5^\circ, 45.5^\circ, 65.5^\circ, 77.5^\circ$, and 117.5° , corresponding to the diffraction on the crystallographic planes (111), (200), (220), (311) and (420). Moreover, we can distinguish another diffraction peak appearing at $2\theta^\circ = 47.5^\circ$, corresponding to the crystallographic plane (202) of the nonequilibrium coherent precipitates θ' . This indicates that the base 2219 Al-alloy was subjected to an age hardening heat treatment.^[29,31]

On the other hand, Fig. 8 presents an XRD pattern obtained on the EBW zone of this alloy. It is noted that most of the diffraction peaks corresponding to α phase were decreased with a simultaneous increase in the intensity of the peak corresponding to the θ' phase Al_2Cu . This can be

Fig. 4 Microstructure of the HAZ indicates: (a) Overaging zone and (b) solution-treated zone^[29,31]

explained by the effect of the heat of the weld, which can cause overaging in the zones adjacent to the base metal and solution followed by precipitation of the equilibrium θ phase along the grain boundaries upon cooling in the zones adjacent to the fusion zone.^[29,31]

Effect of Welding Conditions on Fracture Surface

To understand the fracture mode and to characterize the fracture features, the fracture surfaces of the optimum tensile tested specimen were examined using a scanning

electron microscope (SEM). SEM micrographs are taken from the top of the weld (Fig. 9). At low magnification, the fracture surface is interdendritic brittle fracture through the weld bead. We can distinguish some areas characterized by the existence of fine dimples indicating ductile fracture mode. Micro cracks were observed on the fracture surface; these cracks appear to be along equiaxed grain boundaries. These types of cracks are known as solidification cracks.^[35] At high magnification, dimples with various size have been found in Fig. 10; fine equiaxed dimples are found in the upper part, while elongated dimples are observed in the lower part.^[29,31]

Electron-Beam Welding of Thick Components of Steels, Aluminum, and Titanium Alloys

V.N. Martynov, A.S. Khokhlovskii, and A.P. Sliva

Moscow Energy Institute, Technical University, Moscow, Russia

Abstract

In this paper, conditions for vertical weld defectless formation at horizontal electron-beam welding (EBW) are shown and power-complex selection methods to weld thick-walled constructions by electron beam are developed. Dependences to estimate EBW optimal conditions are obtained.

Keywords: Electron-beam welding; Power complex; Procedure; Weld seam formation.

Because of the high energy concentration in the electron beam, simple control of the beam by magnetic and electrical fields and the application of vacuum-shielding electron-beam welding (EBW) occupy a special position in various branches of engineering. In energy and power engineering, the electron beam is used for welding packets of blades, diaphragms of turbines, bodies of reactors, and heat exchanger equipment; in aircraft construction, it is used for welding components of the engine and the airframe; in chemical engineering, the method is used to weld high-pressure vessels, pipelines, and various equipments; in automobile construction, it is used in the production of the gear blocks, rear axles, sections of the transmission boxes; and in instrument making, it is used in the production of membranes and bodies of various devices. EBW is also used in the production of welded pipes, pumps and ventilators, electric engines, etc.

Because of the low heat input, the thermal cycle in EBW is characterized by high heating and cooling rates and also the short time during which the metal is subjected to high temperatures. In comparison with arc welding, EBW is characterized by the smaller weld zone and by the delay in the development of structural changes and deformation.

The application of vacuum shielding in EBW reduces the extent of surface contamination and the amount of adsorbed water and liquid films, thus increasing the plasticity and corrosion resistance of the weld metal.

The application of EBW increases productivity, reduces the consumption of structural and welding materials, and also reduces the electric-energy requirement, which is especially important in the production of large thick-walled structures.

The results of investigations of EBW of thick-walled components with the horizontal beam and the joint in the vertical position show that high-quality welded joints with continuous penetration can form only in specific welding

conditions, if these conditions are not adhered to defects in the form of cavities that may appear in the welded joints.

The stability of free formation is determined by the condition of maintaining the weld pool in equilibrium:^[1]

$$\sqrt{v_{cr}} - \sqrt[3]{\frac{8\pi\sigma K_1^2 A_2^2}{K_2 \rho g h A_1^2} \frac{\sqrt[6]{v_{cr}}}{d}} + 4K_1 \frac{A_2}{A_1} \frac{1}{\sqrt{d}} = 0, \quad (1)$$

where v_{cr} is the critical welding speed resulting in stable formation of the welded joint, σ is the surface tension coefficient of liquid metal, ρ is the density of metal (kg/m^3), g is the freefall acceleration (m/s^2), d is the electron-beam diameter (m), and K_1 is the experimentally determined coefficient.

The critical-beam diameter is

$$d_{cr} = \sqrt{\frac{2\pi\sigma}{27K_2\rho g}}. \quad (2)$$

The coefficients

$$A_1 = \rho[c(T_m - T_0) + L], \quad (3)$$

$$A_2 = (T_m - T_0)\sqrt{\lambda c \rho}, \quad (4)$$

and

$$K_2 = 1 - \left(\frac{T_m - T_0}{T_b - T_0} \right), \quad (5)$$

where c is the specific heat content of the welded metal (J/kg K), λ is the coefficient of heat conductivity of the metal (W/m K), T_m is the melting point (K), T_0 is the temperature of the environment (K), T_b is the boiling point of the metal (K), and L is the specific heat of melting of the metal (J/kg).

Fig. 1 Dependence of the electron-beam diameter on the critical welding speed: (1) titanium alloy, (2) aluminium alloy, and (3) steel

The results of calculations carried out using Eq. 1 for a pearlitic steel, titanium, and aluminium alloys are presented in Fig. 1.

The energy balance of the EBW process can be described by the following equation:^[2]

$$W = \frac{H}{\eta_e \eta_t} (A_1 v d + 4 K_1 A_2 \sqrt{v d}), \quad (6)$$

where W is the beam power (W), H is the thickness of the component (m), η_e is the effective efficiency of welding, and η_t is the efficiency in butt welding of sheets with a rapidly moving linear heat source.

Since EBW uses the energy of deceleration of the accelerated electrons, the process of formation of the penetration channel is influenced mainly by the parameter of the electron beam – the minimum diameter $d_{\min}$ and the angle of convergence α . High-power welding guns produce beams with the minimum diameter of $0.5\text{--}1.4 \times 10^{-3}$ m and the angle of convergence of $1\text{--}2 \times 10^{-2}$ rad. In penetration of the focal plane to the value S from the surface of the component within the limits of the thickness H of the component, calculations can be carried out using the following equations:

$$d_{\text{mean}} = d_{\min} + \frac{(H - S)^2 + S^2}{H} \alpha \quad (7)$$

and

$$d_{\max} = d_{\min} - 2 \frac{(H - S)^2 + S^2}{H} \alpha. \quad (8)$$

Evidently, to calculate the mean width of the welded joint and the required power, it is necessary to use the mean diameter of the electron beam d_{mean} ; but in the calculations of the stability of formation of the welded joint (Fig. 1), it is essential to consider the maximum diameter $d_{\max}$ because, the stability of formation of the welded joint is disrupted in the areas where the width of the welded joint has the highest value.

The above considerations were used in the development of a calculation method for predicting the optimum conditions of EBW with a horizontal beam. These conditions result in the formation of defect-free welded joints and can be used to select the energy system for welding specific components (Fig. 2).

In the selection of the welding gun for EBW with continuous penetration and free formation of the welded joint for a specific component, the first stage consists of the determination of the values of d_{cr} and $d_{\max}$ followed by comparison of these values. If $d_{\text{cr}} > d_{\max}$, the welding speed is selected in the range of $v_{\text{cr1}} < v < v_{\text{cr2}}$ and the power W is determined; if $d_{\text{cr}} < d_{\max}$, it is necessary to use a different welding gun with a lower value of $d_{\min}$ or α .

The conditions in the experiments with the EBW of steels, titanium, and aluminium alloys are selected using the proposed procedure. The values of the wall thickness of the component are used to calculate the optimum conditions with a focus on the level of half the thickness of the specimen and this is followed by correction in the direction of increasing the power by 5–10% in comparison with the calculated value in order to guarantee continuous penetration.

Welding was carried out using an ELA 60/60 energy complex. The critical diameter in EBW pearlitic steel 12Kh2MFA with a thickness of 70 mm is only 0.1 mm greater than the maximum diameter of the electron beam, which at the welding speed is slightly different from the optimum speed results in the discharge of liquid metal from the weld pool and in the formation of defects. The favourable combination of the thermophysical properties and the low density of titanium and aluminium alloys

Fig. 2 Diagram of calculations of the parameters of the EBW conditions

Fig. 3 Macrosections of welded joints: (a) steel 12Kh2MFA, $H = 70$ mm, $U_{acc} = 60$ kV, $I_b = 300$ mA, $\nu_w = 8$ m/h, (b) OT4 titanium alloy, $H = 95$ mm, $U_{acc} = 60$ kV, $I_b = 280$ mA, $\nu_w = 8$ m/h, and (c) 1201 aluminium alloy, $H = 75$ mm, $U_{acc} = 60$ kV, $I_b = 400$ mA, $\nu_w = 12$ m/h

result in the formation of high-quality welded joints when using the ELA 60/60 equipment for components with the wall thickness of up to 140 mm.

The macrosections of the welded joints in the steel, titanium, and aluminium alloys are shown in Fig. 3.

EBW can be applied only in discontinuous penetration or when using a backing sheet. To prevent the discharge of the weld pool, the gap between the component and the backing sheet should not be greater than 0.3 mm^3 .

In electron beam welding in the flat position, when the penetration channel is stationary or moves uniformly, the equilibrium for the element of the pool subjected to the effect of gravitational force, surface tension, and vapour pressure is determined by the following equation:^[3]

$$\rho gh + \sigma \left(\frac{1}{R_1} + \frac{1}{R_2} \right) = p_s + p_d, \quad (9)$$

where h is the distance from the investigated element of the pool to its surface (m), R_1 and R_2 are the main radii of curvature of the element of the surface (m), p_s and p_d are the static pressure and dynamic pressure, respectively, of the metal vapours in the channel.

The static model of the processes of EBW in the flat position can be used, because the vapour channel shape is stable with time and metal transfer takes place without any change in the shape of the channel, which only oscillates.

Increasing h increases the left part of the relationship, because the width of the pool and one of the curvature radii decrease or remain unchanged, and the maximum value characterizes the root of the welded joint and, consequently, the equilibrium of the base of the pool is ensured

Fig. 4 Macrosection of a welded joint in 12Cr18Ni10Ti steel ($H = 80$ mm, $U_{acc} = 60$ kV, $I_b = 750$ mA, $\nu_w = 15$ m/h)

by the maximum static pressure and the dynamic gas pressure.

The minimum mean melting rate of the lower part of the front wall of the channel, selected from the equilibrium condition of the base of the pool, is also the minimum permissible welding speed. As the thickness and density of the welded metal increase, the minimum welding speed for ensuring equilibrium also increases. In welding at lower speeds, part of the liquid metal of the pool flows into the zone of the effect of the electron beam, is superheated and rapidly evaporates and this greatly disrupts the hydrodynamic conditions of the welding process and leads to a decrease in the penetration depth and the formation of defects in the lower part of the welded joint. Therefore, the conditions of EBW with the vertical beam are selected on the basis of experiments to ensure formation of defect-free welded joints.

The macrosection of the welded joint in 12Cr18Ni10Ti austenitic steel, produced in the flat position in the ELA 60/60 energy complex, is shown in Fig. 4.

Thus, the essential condition for the formation of defect-free welded joints in EBW with the horizontal beam is that the critical diameter should be greater than the maximum diameter of the electron beam: $d_{cr} > d_{max}$. This condition was considered in developing a method of selecting the energy system for EBW of thick-walled structures.

Entrainment Defects

J. Campbell

United Kingdom*

Abstract

Most metals start their lives in the liquid state, and are subjected to various transfers involving pouring or other types of surface turbulence. These actions entrain (fold in) the surface film to create entrainment defects. These are principally (a) bubbles that in turn create bubble trails; (b) bifilms; doubled over surface films, that act as cracklike defects; and (c) sundry entrained debris, collectively known as exogenous inclusions. The bifilm is the subject of this perspective. It appears to be a common, but serious and almost overlooked metallurgical defect. Analysis of bifilms provides a simple, powerful and elegant concept based on an enduring legacy from turbulence during the pouring of liquid metals. Usually large populations of bifilms are introduced into metals at an early stage of their production. In general their presence has been unsuspected because although they can have large area, they can often be only nanometres thick and not easily detected by conventional non-destructive techniques. The populations of cracks in suspension in liquid metal explains many otherwise inexplicable features of cast products such as porosity, hot tearing, the morphologies of second phases, and impaired reliability of mechanical properties. The fundamental difference between such entrained defects (associated with a macroscopic unbonded interface) and defects and inclusions grown in the melt is seen to be of central significance for the failures of metals by mechanical or corrosion type mechanisms. For wrought products the continued presence of bifilms, now usually extended and elongated and mainly occupying grain boundaries, appears to offer explanations for many metallurgical phenomena. Bifilms are likely to influence the development of texture, and are the most likely source for many types of failure in the solid state. Thus the limitations to superplastic forming, cavitation in tertiary creep, pitting corrosion of various types and stress corrosion cracking are likely to be profoundly affected by bifilms. Although the effects of bifilms can be reduced by expensive post-casting operations such as hiping or working, the major future potential lies in techniques for their avoidance. Some casting operations are already taking some first steps in new technology for their avoidance, and benefiting technically and commercially.

PREAMBLE

The subject of entrainment defects is so large, and involves so many aspects of metallurgy, that is it not possible to cover all aspects in this brief Perspective. The reader will also appreciate that much of the matter presented here is so new that a certain admixture of speculation is not easily avoided, and, it is hoped, can be forgiven. Despite the undoubted presence of errors that remain lurking among the facts during these early days of disentangling this complex subject, the understanding of entrainment seems to be emerging as a central plank for our future understanding of the behaviour, not only of cast metals, but perhaps all metals.

It is also useful to bear in mind in this short account that much of the evidence presented here is plain for anyone to

see in many casting operations, but has escaped the attention of the scientific community because it has not found its way onto the printed page. Thus this Perspective would be quite inadequate if it merely reviewed the literature.

For the future, it is hoped that the reader will appreciate that the control of entrainment during casting manufacture has enormous potential for the benefit of metallurgy and mankind.

INTRODUCTION

The presence of oxide inclusions inside metals, particularly those metals that have practically zero solubility for oxygen, is often a paradox. For instance thermo-dynamic considerations predict that not one atom of oxygen will be present in any normal sample of aluminium, so that the

presence of significant quantities of oxides is curious. It is proposed here that such oxides are first created on the surface of the liquid metal, but are transported to their interior sites by the flow of the liquid.

Whereas it is recognised that oxides can be introduced into bulk metals by other mechanical routes such as powder processing (interesting similarities and differences are to be noted with this solid state route), we concentrate here on the liquid processing route as being the most common source of many of our engineering metals.

The filmed surface of a liquid can become entrained in the bulk liquid. The entrainment action is an enfolding of the surface, leading automatically to the folding in and subduction of its surface film (Fig. 1). Such surface turbulence leads to entrainment events that are usually rapid, requiring only milliseconds, so that the creation of new surface, and the time for the formation of new oxide film on this fresh surface, is so limited that the entrained film can be very thin, of the order of nanometres (Fig. 2).

Most films on liquid metals are oxides (although nitrides and carbon films are also common) and most are solid at the temperature of the melt. When entrained,

Fig. 1 Schematic representation of surface turbulence causing the entrainment of bifilms and associated bubbles. Small entrained bubbles form pores that decorate the bifilm, crack AB, whereas large bubbles, C and D, are buoyant, creating bubble trails prior to capture elsewhere or eventual detrainment

Fig. 2 Multiply folded oxide film of thickness only 20 nm in the central region, seen on fracture surface of Al alloy (courtesy N. R. Green)

the dry surfaces of the films fold, necessarily facing each other and cannot bond, being a ceramic to ceramic interface, thus constituting a crack (feature AB in Fig. 1) in the liquid. Most pouring actions involve such severe surface turbulence that they fill the liquid with doubled over films that act as cracks. The entrained film is necessarily double, hence its name 'bifilm'. Its double nature is seen clearly in the 'butterfly wing' patterns on opposing halves of fracture surfaces (Fig. 3) and in places where sections have by chance in places polished part way through a tangled form of the defect (Fig. 4).

Other actions that can entrain different kinds of bifilms are reviewed elsewhere.^[1] These include the entrainment of bubbles; small bubbles remaining trapped in the original bifilm, whereas larger bubbles (for instance C and D in Fig. 1) are powered by their buoyancy to create long bifilms of a collapsed tubular geometry, called bubble trails. (These oxide lined channels through the matrix explain many of the leakage problems common with aluminium alloy cylinder head castings.) The rising bubbles also wreak additional damage to the dendritic structure of the solidifying casting. Since in the case of many castings the films are usually oxides that are stable and insoluble in the melt, the damage is long lived, if not permanent.

The cracks are usually invisible and often undetectable by most techniques because the surface oxides are usually only a few molecules thick, approximately 20 nm (Fig. 2), even though they may be square millimetres or square centimetres in extent. The author has witnessed folded films in a large Ni based alloy casting that were fractions of a metre across. The double films became visible on a radiograph in this case because they had been opened up by the action of the shrinkage on solidification. The radiographer had been trained to identify such images as shrinkage porosity, which, in a sense, was correct, but not helpful to identify a remedy. The association of the porosity with a bifilm led to a different solution compared to that which would have applied for simple shrinkage.

This experience identifies one of the answers to the question: 'If bifilms are so common, how is it that they have been universally overlooked until now?' The fact is that they are difficult to detect with our normal metallurgical techniques.

Even so, the team in the author's laboratory are becoming skilled at identifying oxides on fracture surfaces using SEM. Despite decades of experience of the use of SEM in examining fractures, at once time we were not aware of the presence of bifilms, and saw none. Now we know what to look for, we find them in profusion on nearly every metal fracture surface examined. Furthermore, the bifilms are sometimes so extensive that they cover 100% of the fracture surface. (An example in Fig. 12a,b is described later.) They remain largely invisible even in the SEM because they are so thin that the structure of the metal is clearly seen through the film. The presence of a film is seen only at the highest magnifications, in which the characteristic

Fig. 4 Tangled bifilm seen on polished surface because it is relatively old and thick. Its double nature can be seen in places where top regions of the bifilm have been removed to reveal underlying half of bifilm (courtesy M. Divandari)

creases and folds identify the presence of a defect that can be identified as a film generated on the liquid surface. Its near mirror image resides on the opposite fracture surface, and can often be seen as the ‘butterfly wing’ pattern if the fracture surfaces are placed together. Its characteristic fluorescence in the electron beam, and chemical composition are further identifying characteristics.

However, a second important reason for our lack of awareness of the existence of bifilms lies in our standard investigative metallurgical techniques. In general, the optical microscope is usually not capable of resolving bifilms, and the transmission electron microscope (TEM) samples only such a small volume of material that the chance of the sample containing one of these defects is small. Even if there is a bifilm in the sample, the preparation process for the production of a sample sufficiently thin to be viewed in the TEM is likely to attack the bifilm preferentially because it behaves as a crack. Thus the defect is opened up and destroyed in the sample preparation process. In addition to these important factors, most metallurgists spend their days investigating wrought materials in which the bifilms have been closed (but not always bonded) by the working process, and so not easily detected.

Conversely, bifilms are easily opened and observed when the metal is in the liquid state. Although physical metallurgists have not normally investigated this state at this time it is a powerful approach that is strongly recommended for adoption as a routine future standard. It is described briefly below.

Fox and the author^[2] assumed that there would be a thin layer of air (or residual gases) trapped between the halves of the bifilm. The gas would be retained both in the minute surface roughness, and in the larger irregular folds and creases. They predicted therefore that if the pressure above the melt were reduced by a factor of 10, the gas entrained between the halves of the bifilm would be expanded by 10 times. The pressure was reduced to 0.01 atmosphere and so expanded the bifilms by 100 times. The bifilms then expanded sufficiently to become clear in a radiographic study (Fig. 5).

Thus when we look for bifilms they can usually be found, and found in large numbers. In aluminium alloys a concentration of 10^9 m^{-3} (1 per cubic millimetre) appears average, whereas even 10^{11} m^{-3} (100 per cubic millimetre) is relatively common.

As an alternative quantifying measure, the total length of bifilms in a standard sample can be measured. A convenient standard sample is that produced by the reduced pressure test, weighing approximately 100 g. When sectioned vertically through its centre and polished its area of approximately $35 \times 35 \text{ mm}$ can be scanned using, for instance, an automated metallo-graphic system. In this way the number and average maximum length of defects can be counted. Such checks might reveal the total length of bifilms on the sampled surface to be only 0 to 1 mm in a high quality melt, whereas a much less good total of 50 mm is more common. However, sometimes the length approaches half a metre.^[4] The latter figure corresponds approximately to an area of 5 mm^2 of bifilm per cubic mm.

The technique has also been applied to quantify the number and the length of bifilms in solid metals. A sample of the solid (of volume perhaps around 10 mL) is placed in a small crucible and the remaining space in the crucible is packed with sand or refractory powder to ensure that the

Fig. 5 Comparison of X-radiographs taken at same time after pouring from same melt of Al-7Si-04Mg alloy subjected to solidification under pressure (a) 1 atmosphere, showing diffuse images of furred bifilms; and (b) 0.01 atmosphere showing unfurled bifilms^[2]

sample retains its shape and is undisturbed during melting. The sample is then melted by placing the crucible in a muffle furnace. Once melted, the sample is subjected to the accurately reduced pressure and is solidified once again. The sample is then studied by sectioning or by radiography^[2,4] It is relatively quick, and, sometimes, soberingly informative.

The work by both Fox^[2,3] and Dispinar^[4] illustrates not only the wide spectrum of numbers and sizes, but also that populations of very different sizes of bifilms occur because of different melt conditions. In addition, different populations accumulated from different stages of manufacture often coexist in the same sample.

It is important to keep in mind that bifilms are not always oxides. Sometimes they are nitrides, sulphides, amorphous carbon, graphite or other materials. They are also not always solid, but can be partly solid, or even liquid, and in some cases not present at all. When they are present, as is usually the case, they can to some extent be controlled in numbers by careful handling of the liquid metal. The performance of whole commercial casting operations has been revolutionised by attention to the metal handling and pouring practices. The production of scrap castings has been reduced, and improvements to properties obtained simultaneously, usually with a reduction in costs.

This Perspective examines the evidence for bifilms and their numerous effects. The potential for the improvement of properties of metals without bifilms can to some extent be predicted by extrapolation. The prospects appear to be of wide application and great significance, and probably justify the next major effort in the future of metallurgical processing.

ENTRAINMENT

The entrainment of the filmed surface of a liquid occurs when some of the area of the surface is lost.

The loss can occur by the folding over of the surface. When considering Fig. 1, the breaking waves are clearly increasing the surface area of the liquid up to the instant that the folds close, sealing the bifilm (and possibly bubbles, or other debris if present) into the bulk liquid. At that instant that area of bifilm is lost external surface area. It has become an internal surface.

The criterion for this case is a critical Weber number ($We > 1$), in which the inertial forces in the liquid that are tending to perturb the surface exceed the surface tension forces that tend to restrain the surface, holding it in a compact form. In practice, the condition works out to be equivalent to a critical velocity, above which the surface can be propelled upwards, achieving a height sufficient that it may enfold its surface as it falls back under gravity. This critical velocity is in the region of 0.5 m s^{-1} for nearly all liquids, and is a useful parameter that is now being built in to many filling system designs for castings, with excellent results if carried out correctly.^[1,5]

A second mechanism for loss of surface is merely the contraction of the surface, as happens for instance as the surface expands and contracts because of random perturbations.^[1] Such disturbances occur continuously in many melting operations. Each time the surface expands more film area is created as its area stretches. However, each time it contracts, the newly created oxide raft cannot contract, and therefore must fold, crumpling concertina fashion. With continuing disturbances of the surface the folds lengthen irreversibly in a kind of natural ratcheting

mechanism. Eventually they will become sufficiently long to be dragged into the bulk liquid.

Clearly, the casting industry needs techniques that avoid the introduction of such damage. At the present time every pouring event violates the critical velocity criterion and introduces oxides to the melt. This is simply the result of the acceleration under gravity causing the critical velocity of 0.5 m s^{-1} to be exceeded if the fall of the liquid exceeds only about 10 mm. Thus at the least, pouring transfers require to be reduced, and if necessary, the damage introduced requires to be reduced or reversed by additional treatment. However, there are now casting systems for which pouring is eliminated in the whole operation, with significant benefits to properties and reproducibility of products.^[6]

One of the central features of the entrainment of the surface is that the events are cumulative. For instance, for Al alloys the first turbulence suffered by the material often occurs at birth, at the Al smelter. This first addition of bifilms is supplemented by a second population introduced by the pre-alloying producer.

Several more populations follow in the foundry by melting, pouring into a transfer ladle,^[1,3] and finally pouring into the mould. Naturally, some of the original defects are lost by sedimentation or flotation, or by attachment to the walls of containers. Some may be lost by filtration, although it is known the filters have only limited ability to trap inclusions.^[1] The remelting of foundry returns, or even machining swarf, simply adds to the total.

However, in this way Al alloys are special. They have a surface oxide film that is marginally more dense than the liquid, but the entrained air in the bifilm means that many defects have near neutral buoyancy. This feature, combined with the nearly zero Stokes velocity because of the high drag factor provided by its film morphology, means that separation by floating or sinking is especially slow, taking hours or days in conditions where the melt is gently convecting, or, in the case of induction melting, strongly stirring.

In addition to the problem of the slow separation by buoyancy when suspended freely in a liquid, the situation becomes much worse when the density of defects is such that they form an interconnected latticework throughout the melt. Such a situation is seen in an Al alloy in Fig. 5. These frameworks in the liquid are expected to be rather stable with time, since the mutual contacts mean that flotation or sedimentation is now difficult. Whereas most liquid metals and alloys (containing normal populations of defects of interest in this account) pour rather like water, because the viscosity of most engineering metals is not significantly different from that of water, the sight of a melt, at a temperature well above its melting point, pouring like porridge is, regrettably, not that uncommon. It is a sign of the presence of an extremely high density of defects. (The mechanical properties of such cast material have not been reported in the literature, but in the experience of the

author, are extremely poor, much poorer than the impaired properties discussed later in this account.)

Such viscous metal matrix composites do not convect when solidifying in a mould, with the development of quite different grain size since dendrite arms are not melted off in convective disturbances. This mechanical problem (in addition to other metallurgical factors such as the presence or absence of nuclei etc.) seems to be one of the major reasons for the development of large grain size in some casting conditions as is discussed below. In addition, the mechanical barriers separating parts of the melt lead to locally isolated conditions, some regions evidently being devoid of nuclei, allowing local supercooling and fine dendrite arm spacing (DAS) adjacent to regions of coarse DAS (Fig. 6). This can happen, of course, because it is well established that most metals can be supercooled by hundreds of degrees kelvin in contact with oxide refractories.^[7,8] Such extreme isolation of parts of castings is certainly common in cast aluminium alloys, because thousands of tonnes of dross per day are produced in aluminium melting operations only by the gentle action of the skimming of the melt.

Fig. 6 Fine and coarse DAS located adjacently in an Al–Si alloy, regions isolated by bifilms (a) decorated with silicon precipitates, and (b) without significant silicon precipitation on the bifilm barrier (courtesy D. Dispinar)

(Dross is metal that is wrapped up in oxide skins so effectively as to be inseparable without the work of special dross recovery operations. Dross can be over 80% metal.) Thus the jetting and splashing that accompanies most casting operations easily achieves such disintegration into permanently separated volumes.

Some stainless steels, particularly the super duplex stainless types, have particularly strong and tough oxide films that create macroscopic problems when pouring; bifilms are found, on occasions, to form a linked network completely through cast walls over 100mm thick. These are first indicated by radiography as areas of apparent shrinkage or sponge porosity. However, when the material is excavated by grinding and tested by dye penetrant it reveals the appearance of a spider's web of cracks. If the casting is to be salvaged such material has to be completely dug out and refilled with weld metal.

Most other metals are not so disadvantaged. For instance in the case of carbon/manganese steels, entrained defects are very different in density, providing a significant driving force for separation by flotation. However, when generous quantities of aluminium are used for deoxidation, the entrained alumina films still have a high drag because of their aspect ratio and so separate slowly. (It is appreciated that we may need to be careful here to distinguish these entrained inclusions from any source of alumina that may nucleate and grow in the steel matrix, particularly during solidification.)

However, if the steel is deoxidised with Ca after the Al addition, the surface film of solid alumina is converted into a low melting point eutectic of mixed alumina and calcia. The folding in of this surface film is then simply the conjoining of two liquids that immediately mutually assimilate, forming droplets, and so float out with maximum speed. Calcium treated steels are known to be much cleaner than steels simply deoxidised with Al.^[9] In addition, those residual oxides that do not detrain are spherical in shape as a result of their liquid nature during the solidification of the steel.^[10]

Other steels, particularly the common carbon and low alloy steels, have surface oxides that are partly liquid because of their composition and because of the high casting temperatures. An entrainment event now results in the surface film adhering to itself as it is ravelled up by the internal turbulence in the liquid. The entrained film therefore becomes a compact sticky ball. This bifilm cannot unfurl again, being glued closed. It can therefore float out quickly, forming the large drossy or slaglike defects sometimes known as re-oxidation defects, centimetres in diameter, that decorate the cope surfaces of large steel castings, and that require to be laboriously dug out and backfilled with weld metal.^[11] Many steel foundries notoriously have more people in the so called upgrading shop than in the foundry, and jokes about the use of more weld metal than cast metal in castings production are common in the steel casting industry.

The sharp difference in behaviour between cast Al alloys and cast steels is probably highly significant. The rapid detrainment of bifilms of various types in steels explains their generally high levels of cleanness, and their high ductilities, usually between 25 and 50%. Cast Al alloys often have high levels of bifilms because they are so sluggish to separate, resulting in ductilities often measured in low single figures, or even 0%. Only in the last few years, using extremely careful handling with specially designed plant, have higher levels of ductilities in cast Al alloys been reproducibly produced in the range 10 to 20%. The prospects for matching the ductilities of steels are beginning to seem achievable.

FURLING

The ravelling of the entrained bifilm into a compact mass is almost certainly a standard feature of the history of each bifilm. This is because if the liquid surface experiences sufficient energy to create an entrainment event (i.e. $We > 1$) the internal turbulence in the liquid (i.e. beneath the surface) will also be experiencing bulk turbulence (i.e. $Re > 2000$). Because the bifilms are diaphanously thin, they have little rigidity of their own, so they are easily wrapped up by the turbulent eddies in the flowing liquid. As they tumble along channels into a mould they will be expected to continuously ravel and unravel in different ways.^[1] A section through a convoluted bifilm is shown in Fig. 4. Radiographs of such compacted bifilms^[2] are seen as faint, diffuse images in Fig. 5.

In this compacted, convoluted form a large bifilm may be able to pass through a relatively fine filter, explaining to some extent the partial effectiveness of filters.

Also, while the bifilm is 'furled' in this way, any deleterious effect on mechanical properties of the solidified cast metal would be expected to be minimised; its effective crack length is minimised, and the effect of the crack reduced because of the mechanical interlocking of its complex form. (The bifilm only develops its maximum damaging effect later, as is described in the next section.)

In the meantime, while experiencing the turbulence characterised by the high Reynolds number, depending on its tensile strength, the film may resist tearing or may be shredded into many smaller fragments. In any event, careful thought indicates that its bifilm nature (i.e. its double film form) is not expected to be impaired. The two halves of the bifilm will be strongly encouraged to remain in contact by various co-operating factors, including the hydrostatic pressure in the melt, the viscous adhesion effect between parallel plates separated by a thin layer of air, and the short range forces between the contacting surfaces. In any case, even where locally torn away, a double film will be expected to repair locally by creating a new film, oxidising the newly created liquid surface from the reservoir of air in the bifilm.

UNFURLING

Once the pouring phase of a transfer is finished, or a casting operation is complete so that the melt has arrived in the mould, internal turbulence subsides, and a period of quiescence follows. During this period the bifilm may experience a number of influences, as described below, that quietly force it to unravel, opening fold by fold, until it forms a substantially planar cracklike defect close to its original size when first entrained.

This unfurling of the compacted defect is a critically important stage. This process defines the properties of cast materials. For instance, in the simplest case, after the filling of the mould, if freezing occurs quickly, the bifilms are frozen in as convoluted cracks of overall small, compact shape, rendering them relatively harmless. Mechanical properties are therefore usually good. However, if freezing occurs slowly, the bifilm has time to unfurl, expanding to take up its full size as a planar crack and so reducing properties. Every foundry person making light alloy castings knows that the properties of chilled castings are better than those of slowly cooled castings.

There are a number of reasons why bifilms unfurl, tending to return to their starting size. The unfurling mechanisms are discussed in turn below.

Gas Precipitation from Solution (Formation of Gas Porosity)

It is worth emphasising that porosity in liquid metals cannot occur as a result of classical nucleation processes, such as those involving the rearrangement of atoms (alternatively stated, the condensation of vacancies) to create an embryonic bubble. The impossibility of homogenous nucleation is of course widely accepted. What may be less easy for some to accept is that classical heterogeneous nucleation, although clearly significantly easier, is still not sufficiently easy to make pore nucleation possible in cast products.^[1] For instance, the most non-wetting condition observed experimentally corresponds to a contact angle of approximately 160° . This value, when substituted in the classical formulae for heterogeneous nucleation,^[12] yields a reduced pressure for nucleation by a factor of 20. Although this is a large reduction, it is not large enough to facilitate nucleation on any common non-wetted substrates in any known liquid metal.^[1]

In other words, interfaces in atomic contact are probably impossible to separate in any practical circumstance. This is because, despite any degree of wetting (i.e. assessed macroscopically by such concepts as contact angle) on an atomic scale, the bonding between atoms is sufficiently strong to be inseparable in any conceivable practical situation.^[1] It is worth reflecting that all phases grown in the liquid have grown atom by atom and so are necessarily in perfect atomic contact with the matrix. Thus none of these can be favourable substrates for pore formation or decohesion.

Fig. 7 Inclusions entrained via the surface carrying their coating film, so that they are unaware of being submerged in a melt. A trail of bifilm can also be associated, as illustrated here

Conversely, if an interface is not in atomic contact with the liquid, the separation of this interface would be expected to be an easy initiation site for a pore or for a decohesion event. However, such an interface cannot have been grown in the liquid. It must therefore have been an entrained interface. As such it will be separated from the liquid by an unbonded oxide film, together with a separating layer of residual entrained gas. Fig. 7 illustrates how entrainment always introduces non-bonded interfaces, making such inclusions fundamentally different from those grown in the melt or in the solid.

Entrainment defects represent the easiest possible initiating features, since their substantially parallel and unbonded faces can be separated with minimal effort. (Conventionally, but not particularly helpfully, they can be said to have a perfectly non-wetting behaviour characterised by 180° macroscopic wetting angle.) Other initiating solids such as a piece of furnace refractory or any other externally originating material also has to pass through the filmed surface of the liquid and so will have automatically gained its 'paper bag', its wrapping of unbonded oxide film. This unbonded interface can open as illustrated in Fig. 8. All such unbonded, entrained interfaces will constitute excellent initiation sites for pores.

However, it can be quickly appreciated that the separation of these parallel unbonded films does not resemble nucleation in the classical sense. The pore is not created by atomic rearrangements, but pre-exists in the form of a macroscopic film of gas between unbonded surfaces. Also, of course, no 'nucleation barrier' exists as in the case of true nucleation phenomena, no critical embryo exists, and no surface tension or surface energy considerations apply because no liquid surfaces are involved.

Fig. 8 Unfurling and inflating of bifilms: (a) simply folded bifilm; (b) tangled convoluted bifilm; (c) overinflation of a bifilm resulting in spherical pore; and (d) the overinflation of a bifilm late in solidification resulting in an interdendritic pore

In detail, in terms of the present thinking, gas in solution in the liquid metal can conveniently precipitate in the entrained gas film inside the bifilm. Naturally, gas in solution in the liquid will diffuse through the alumina film into the central bifilm gap until the gas in this location reaches the pressure in equilibrium with the liquid. In this way the bifilm is expanded. Its originally compacted form is opened fold by fold until fully extended (Figs. 8a,b). Continued precipitation of gas will, of course, lead to the further expansion of its volume, hinging the two films apart, leading to the growth of a macroscopic spherical bubble having dimensions larger than the originating bifilm (Fig. 8c). If the continued expansion of the bifilm occurs at a late stage of solidification, its expansion is constrained by the presence of surrounding dendrites, so forming interdendritic porosity (Fig. 8d). It can be immediately appreciated that the conventional division of round pores being attributed to gas, and interdendritic pores to shrinkage is not correct. The different morphologies merely result from one pore opening early and the other late during the progress of freezing.

The author has estimated the rate of unfurling with a simple model illustrated in Fig. 9. If we assume that unfurling of a square fold of area $R \times R$ is resisted by the viscosity η of the liquid, we can assume that the force F is of the same type as that resisting the motion of a sphere as in Stokes' law. Thus the force would be $3\pi\eta RV$ if it were evenly distributed over the face of the fold. However, if the velocity V applied only to the tip of the unfolding area, on average the resisting force is $3\pi\eta RV/2$. The unfurling effort

Fig. 9 Model of bifilm involving micro-inflation providing the driving force for unfurling^[1]

is provided by the gas pressure P in the gas phase of the bifilm acting over the small area hR . Equating moments we have

$$2PRh\left(\frac{h}{2}\right) = 3\pi\eta RV\left(\frac{R}{2}\right)$$

so that we can find the time t to unfurl from the speed V and the half circumference distance travelled πR

$$t = \left(\frac{3\pi^2}{2}\right)\left(\frac{\eta}{P}\right)\left(\frac{R}{h}\right)^2$$

Substituting some reasonable values for a bifilm in liquid aluminium of viscosity $\eta = 10^{-3} \text{ N s m}^{-2}$, the precipitation of hydrogen at 0.2 atmosphere (0.02 MPa) inside a $1 \mu\text{m}$ thick layer of air between the films will cause a folded 1 mm long bifilm to fully extend in approximately 1 s. If the fold were 10 mm long and the air gap only 500 nm the unfurling would take 5 min. These estimates of unfurling times are seen to be of the same order as the solidification time of many of our engineering products. Thus the opening of a significant proportion of the bifilm population is to be expected during the solidification of most castings. Also, the rate of unfurling is seen to be highly dependent on the gas content and on accidents of geometry of the bifilm as might be expected, and is suggested by the parameter $(R/h)^2$. This extreme sensitivity to random starting conditions explains many features of porosity in cast products.

One clear example of the variation in unfurling rates for bifilms is seen in the fascinating morphology of subsurface porosity in castings. This is a common condition in which an array of pores lies just 1 or 2 mm under the surface of the casting. They are grown by the flux of hydrogen diffusing into the casting from reaction between the metal and its mould environment as a result of the thermal degradation of its organic binder (Fig. 10a). The pores grow therefore in a rather uniform environment of hydrogen flux. The 1 to 2 mm depth is almost certainly the result of the increasing concentration ahead of the advancing interface, as snow gradually piling ahead of the snow plough, until a critical

Fig. 10 SEM images of subsurface porosity in an Al-7Si-0.4Mg alloy around a sand core bonded with a phenolic urethane binder. (a) General view; and close-ups of (b) a smooth spherical pore; and (c) an irregular dendritic pore (courtesy of Simon Fox and Ashland)

concentration is reached at which the pore can form.^[1] However, curiously, the pores do not grow to a uniform shape and size. Some display a round morphology like a bubble (Fig. 10b), while others have a dendritic morphology that might be assumed to be a shrinkage pore (Fig. 10c). Clearly

the round pores have nucleated early while still surrounded by liquid, but the dendritic pores have formed late, after the dendrites have formed. These differences in the time of the initiation of the pores cannot be the result of differences in growth conditions, since the pores often lie adjacent, and the hydrogen flux will be uniform as a result of the high rate of diffusion of hydrogen in aluminium. It is surmised therefore that they are all hydrogen pores, their differences in morphology resulting from substantial differences in the ease of initiation, in agreement with our expectations based on the randomness of the turbulent compaction of bifilms leading to the random difficulty of unfurling.

Work at Alcan Kingston Laboratories^[13] illustrated for the first time that in cast Al-7Si-0.4Mg alloy at short solidification times the number density (number per unit volume) of pores observed on a polished planar section increased with increasing hydrogen content. Conversely, at long solidification time, the number density of pores decreased as hydrogen was increased (Fig. 11a). This result has remained unexplained for years. Recently^[1] a straightforward explanation has been proposed by the author based on the unfurling of bifilms. The bifilms were assumed to respond initially to the ingress of hydrogen by a process the author has called micro-inflation, in which, in the early stages of inflation, prior to any significant unfurling, many folds were expanded within the compactly folded defect. This created, when sectioned for metallographic examination, the appearance of a cluster of small pores (both the top left and corner, and the bottom right hand corner of Fig. 11b). Only later, with continued inflation, would the compact bifilms open fully, then creating only a single pore. These opening sequences would have symmetry with time and gas concentration, so that too little time or too little gas would give very few pores. If either gas or time were increased the number of pores would appear to grow because of micro-inflation. If both gas and time were greatly increased full inflation would result in only one pore being finally observed (top right hand corner of Fig. 11b). It is not easy to see how any other mechanism could account for such complex pore growth behaviour.

Anson and Gruzleski^[14] report experimental evidence for such a mechanism. Although they assumed that the clusters of small pores were shrinkage pores, their results clearly indicate that as gas in solution in the alloy increases, the volume of pores in the cluster grows at the same rate as the larger separate pores, revealing their nature as entrainment defects inflated by gas precipitation.

In general, it seems that gas pores form only from the opening of bifilms or other entrained unbonded interfaces. In the absence of suitable substrates such as bifilms, the gas cannot precipitate, and so remains in supersaturated solution. It has been a well known fact in casting operations for many years^[15] that filtration can improve the soundness of castings. (Occasionally this has been interpreted as the ability of a filter to filter out hydrogen!)

Fig. 11 (a) Relation between hydrogen content and solidification time (assessed as DAS) found by Major and colleagues;^[13] and (b) explanation based on furled and closed bifilm at short times and low gas levels (lower left hand corner) leading to micro-inflation as either gas or time is increased, giving the appearance of clusters of multiple pores on a polished section. Finally, for long times and high hydrogen levels, the pores fully inflate to give only one pore per original bifilm (upper right hand corner)

Hydrostatic Strain (Negative Pressure) due to Solidification Contraction

Clearly, shrinkage on solidification, if occurring in an enclosed volume, will open the bifilm. In a trapped volume of liquid, during solidification (assuming the solid to be more dense) the accompanying loss of volume will simply expand the bifilms to conserve volume. The result is the typical scattering of micro-shrinkage pores if the effect is modest. If severe, macroshrinkage porosity can result.

(The circumstances are the mirror image of those in which gas drives the unfurling; increase of pressure on the inside is physically precisely equivalent to a reduction of pressure on the outside of the bifilm. Thus it is logical that both gas and shrinkage can act in combination. In the expansion of the bifilm, leading to its unfurling, one pushes from the inside and the other pulls from the outside.)

Uniaxial Strain due to Linear Contraction in the Solid State

If the cast alloy is stretched, as often happens to parts of the casting during freezing, it is clear that the bifilms can

easily be opened. The phenomenon of hot tearing during the solidification of castings has been shown to be eliminated by the reduction of bifilms in the liquid. This is achieved by improving the quality of the melt and providing a filling system design for the casting that does not reintroduce bifilms.^[1]

Dendrite Pushing

The advancing solidification front cannot grow through a bifilm. Although the oxide might be permeable to the metal on a microscale, the layer of air is, of course, impenetrable. Consequently the bifilm is pushed by the advancing dendrites. This is why the majority of bifilms appear concentrated in grain boundaries or in interdendritic regions. If a bifilm is overtaken, becoming trapped inside an advancing array of dendrites while one end remains attached to the wall of the casting, it becomes straightened between the advancing dendrites, effectively unrolled as a roll of carpet being pushed along a floor. Such flat cracks are common in many fields of casting, appearing to be the cause of hot tears.

An example of dendrite straightening is seen on the fracture surface of an Al-4.5Cu alloy in Fig. 12a. The large bifilms straightened by dendrites in this image were observed by video radiography to be entrained during the filling of the mould. No metal to metal contact could be observed on this fracture surface even under close examination by SEM, explaining the lamentable elongation to failure of only 0.3%. The whole surface was found to be covered with a transparently thin oxide film (Fig. 12b). The main dendrite rafts in Fig. 12a are seen to progress from each side of the casting, meeting in the middle. The light, slightly fluorescing regions in the centre of the image were found to be heaps of spare film, pushed ahead of the dendrites, making the north/south ridge across the diameter of the testpiece. In contrast, the more distant part of the same casting, which had been observed in the same radiographic study to enjoy a nicely laminar fill profile, produced 3.0% elongation to failure in the fracture seen in Fig. 12c. The fracture surface was poor, exhibiting many shrinkage cavities, inferring the presence of a high population of smaller bifilms. However, there was some metal to metal contact areas on this fracture surface as witnessed by the patches of ductile dimples that were observed (Fig. 12d).

The grain size appeared to have been influenced by the presence of the bifilms. It seems likely that convection had been suppressed in the presence of the large barriers to flow represented by the large bifilms in Fig. 12a. In contrast, the smaller bifilms in Fig. 12c that had been inherited from the rather poor original melt had allowed the liquid to convect during freezing, thus leading to dendrite fragmentation. It is to be noted that the finer grain size at one end of the casting was not as a result of more prolific nucleation; metals appear to be one of the few solids that do not nucleate on oxides. This behaviour is,

Fig. 12 SEM images of fracture surfaces of a single Al-4.5Cu alloy casting showing (a) the part that was subjected to a turbulent backwave, and the consequential entrained bifilm flattened by dendrite growth. The nearly invisible oxide film covering the whole surface is seen in (b) in a folded area (arrowed). (c) Distant part of the same casting that enjoyed a more tranquil fill, so exhibiting fracture influenced only by the original bifilms in the (rather poor) melt. (d) Areas of ductile dimples confirming true metal to metal contact in the tensile fracture from this second part of the casting (courtesy Jaiwei Mi)

of course, consistent with the pushing phenomenon, and the large supercoolings observable in oxide containers. The effect on grain size appears to result from a purely mechanical effect. This observation serves as a caution to much of our modern work on the prediction of cast microstructures using models based only on such concepts as constitutional undercooling, overlooking the presence of bifilms.

Examples of dendrite straightening in other alloy systems have been reported elsewhere.^[1] These include Ni base superalloys cast in vacuum that display grain boundary facets when cast turbulently,^[16] and in spheroidal graphite cast irons, creating the so called ‘plate fracture’ effect.^[17] The latter is particularly disturbing because so called ‘ductile iron’, marketed especially for its ductility, can unexpectedly exhibit brittle behaviour, fracturing in a brittle manner along large planar grain boundaries. Examples of the remarkable cleavage type fracture along planar grain boundaries are shown by a fracture surface (Fig. 13a) and the equally remarkable polished section (Fig. 13b). The effect is predicted to be controllable, reducing the content of large new bifilms by the improvement of the design of the casting filling system.^[1]

In industrial practice, but, disappointingly, not in the scientific literature, the author can report that there is now much evidence for this mechanism. Hot tears in castings appear to be universally caused by the presence of bifilms, are invariably eliminated by the provision of a well designed filling system. This fact also explains the

Fig. 13 (a) Large planar grain boundary fractures in pearlitic ductile iron casting exhibiting ‘plate fracture’. (b) Polished cross-section taken at right angles to the fracture surface showing the characteristic planar arrays of deformed spheroids and silicon rich regions stabilising the ferrite phase

wide scatter in results that has long troubled the scientific study of hot tearing phenomena since the filling system design for the cast testpieces for such research has usually been poor, without doubt introducing serious quantities of bifilms to cloud results with ‘noise’.

Nucleation and Growth of Intermetallics

It seems that bifilms, at least the oxide film variety that has been mainly observed so far, are favoured sites for the nucleation and growth of a wide variety of intermetallics in

a wide variety of matrices (but not, recall, the matrix phase itself). In fact, the author has found that of the intermetallics precipitating from the liquid so far studied, every one has formed on an oxide substrate. Such precipitation occurs, of course, on one or both of the wetted outside surfaces of the bifilm that originally grew on the surface of the melt. This original growth occurred, of course, atom by atom, resulting in the interface between the melt and the oxide being in perfect atomic contact (effectively bonded to the melt, in contrast to its dry inner, unbonded surfaces). Cao^[18] was the first to report the association between iron rich intermetallics in aluminium alloys and bifilms as substrates. An excellent example of an intermetallic grown on an oxide substrate is the beta iron precipitate Al₅FeSi seen in Figs. 14 and 15. Particles of silicon eutectic seen in Fig. 14 also appear to have formed on bifilms, explaining their central cracks. Strontium rich intermetallics have been observed as having grown on the underside of surface oxide films,^[19] as have carbides in Ni base superalloys.^[20] Those intermetallics that have been studied and are known or suspected to form on entrained films include those listed in Table 1.

The interesting question immediately follows, ‘Are there any intermetallics grown from the liquid that do not form on oxide films’. It seems that a few have probably been identified in special conditions. One possible case involves a new theory by the author for the mechanism of silicon modification based on the finding that these elements appear to deactivate bifilms as favoured substrates for the nucleation and growth of silicon.^[21]

The precipitation of a rigid intermetallic crystal on a rather flimsy film of substrate has interesting consequences. The progressive growth of the crystal can force straightening of the film. However, if the film is thicker, or unable to unfurl because its folds are glued by, for instance, low melting point patches, or perhaps effectively spot welded by high temperature treatment of the liquid,^[22] the

film sometimes dictates that the crystal grows in a compact and/or irregular form. Thus the influence of the substrate on the precipitate or vice versa depends on the relative rigidities of the two, and this can be highly variable, and mixed even within one sample.

Interestingly, there is evidence that the growing intermetallics can be broken up, fragmenting into smaller sections in a kind of particle refining process.^[23] This appears to be the result of the simultaneous precipitation of hydrogen into the bifilm, causing it to inflate and unfold, while the intermetallic is attempting to grow on this mechanically unstable substrate. Southin^[24] suggests an analogous process is happening in the case of solidification of dendrites on a smoke deposited, and therefore fragile, carbon surface. This effect is much used by aluminium casters to increase the apparent fluidity of the melt because a dendrite array cannot build up from the walls of the mould and so impede flow.

Thus the β -Fe phase in Al alloys has a monoclinic structure that grows as platelets. It is renowned for appearing to be brittle as a result of its cracked appearance. Also it greatly reduces the mechanical properties, particularly the ductility, of the alloy. The cracked appearance is proposed here to be the presence of the bifilm; thus all beta particles necessarily contain the oxidised crack on which they nucleated and grew (Fig. 14). Furthermore, it has recently been proposed that the great effect of Fe on the mechanical properties of cast Al alloys is solely caused by the action of the beta phase straightening the bifilm so effectively.^[25]

In contrast, it is well known to metallurgists in the Al casting industry that the addition of an element such as Mn can promote the formation of α -Fe phase rather than β -Fe phase. The alpha phase often takes the form of Chinese script or polygons (Fig. 15). This compact form is less damaging to mechanical properties. We propose here that the compact form is the form of the original compact

Table 1 List of intermetallic compounds that are known or suspected to precipitate on entrained surface films

Liquid matrix	Surface film	Intermetallic compound	References
Al	Al ₂ O ₃	α -Fe (Al ₁₅ Fe ₃ Si ₂)	[18]
		β -Fe (Al ₅ FeSi)	[18]

Fig. 15 SEM images of cracked α -Fe intermetallic phases in an Al-11Si-0.4Mg alloy showing convoluted cracks initiating compact crystalline growth forms. The cracks traverse the ductile matrix in an apparently brittle manner (courtesy X. Cao)

bifilm on which the alpha particle grows. However, there is negligible straightening action because the alpha phase is cubic (or hexagonal), its high symmetry having little preference for any particular growth direction. Sometimes, the polygonal forms of alpha do appear to be adopting some crystalline form, but even in this condition, compaction of the bifilm is not fully reversed. The presence of the convoluted substrate, as a convoluted crack, can still be seen clearly in many intermetallics. In the case shown in Fig. 15 a jagged crack can be seen to extend from the particle into the ductile matrix, where it would normally be assumed that a crack being propagated by stress would simply open in a ductile manner, and therefore blunt and stop. Clearly, this is not a stress related crack.

The similar cracked appearance of primary Si particles were proven by Greer and colleagues^[26] to be the result of solidification phenomena because they noted the occurrence of some eutectic phase inside some of the cracks. Thus the cracks were not, as has sometimes been assumed, the result of mechanical damage during specimen preparation.

MECHANICAL PROPERTIES

The concept of the bifilm allows some explanations of the behaviour of cast products that have been hitherto unexplained. A few examples will be selected.

Reliability and Reproducibility

The simple fact that castings can vary erratically in their properties has never been satisfactorily explained, particularly when, apparently, all steps to eliminate variation have been taken. The variation casting to casting, day to day, and week to week in closely monitored production has been nothing short of baffling. The presence or absence of bifilms in the starting material, and in chance variations in the pouring of the castings have been features that have not usually been suspected.

One of the first clear demonstrations of property variation due to pouring was the experiment carried out by Green and Campbell^[27] in which the manner of pouring was varied. The turbulence of the different systems clearly had a major impact on the reliability of the casting (Fig. 16). In this work Green introduced the use of Weibull statistics to quantify the reliability. Different reliabilities were found for essentially identical alloys poured at identical temperatures, the only difference being the degree of turbulence during this final transfer of metal, and thus the final content of bifilms. (It is to be noted that other damaging features that would have influenced the results, such as porosity, the precipitation of β -Fe phase, and shrinkage, are all consequences of the presence of bifilms, and so are secondary influences.)

The industrial scale experience of the author in setting up the Cosworth Casting Process was significant in this respect. Cosworth cylinder heads suffered 50% thermal fatigue failures on the test bed when using castings made by conventional gravity pouring techniques. After setting up the new countergravity casting process designed to eliminate bifilms (but otherwise using identical casting conditions) failures reduced to zero overnight.^[1]

Green and colleagues^[28] went on to show that the fatigue properties of Al-7Si-0.4Mg alloy were controlled by its bifilm content. In fact in 98% of all fatigue fractures closely observed by SEM in this work, bifilms were the initiators of cracks. The remaining 2% that did not contain bifilms (and whose fractures were initiated by slip planes) exhibited up to 100 times greater fatigue lives (Fig. 17).

Fig. 16 Relative reliability of Al-7Si-0.4Mg alloy cast by different methods, assessed by Weibull plot, showing scatter of tensile strengths^[27]

Fig. 17 Fatigue lives of turbulently filled and somewhat better filled castings, illustrating the dominant effect that bifilms have on the fatigue life^[28]

The author has mixed views concerning those several researches that claim to have found that pores are more important than bifilms in initiating failure, particularly fatigue failure.^[29,30] In a sense the differentiation is, in practice, almost irrelevant since both are entrainment defects, the pore being simply a rather more open type of bifilm.

In addition, of course, the pore definitely has zero cross-sectional tensile strength. In contrast, the bifilm has mixed strength, on average perhaps 50% of the strength of the matrix.^[1] This is the result of (i) mechanical interlocking of folds, and the interference of 'jogs' in the film when subjected to shear, and (ii) variations in alignment; a planar bifilm aligned with the tensile direction will cause no observable reduction in strength, whereas when perpendicular to the tensile axis it could behave as having zero strength. Thus there are reasons why pores may be more

important. However, the films are usually vastly greater in area (for instance in Fig. 1 the pores are seen merely to 'decorate' the bifilm), have a sharp aspect ratio, and are so thin that they are routinely overlooked by observers. Thus when an observer claims to have identified a pore as the origin of a fatigue crack, he has almost certainly failed to notice that the pore is almost certainly a part of a much larger area bifilm, whose presence is difficult to detect because of its thinness and consequent transparency.

The sequel to these findings has been the development of new exciting filling system designs for castings, with great benefits to integrity, soundness, increased properties and the simultaneous reduction of costs on the industrial scale. Most significant has been the improvement in reliability. All these benefits are, of course, highly prized targets in the marketplace. The new approach to the solution of the age old problem of achieving castings as reliable as, or more reliable than, forgings is summarised in a recent text.^[5]

Dendrite Arm Spacing

A second example of a major breakthrough in the scientific understanding of the behaviour of castings has been the relation between dendrite arm spacing (DAS) and elongation to failure of cast alloys. This effect is common to practically all cast metals. A typical example is shown in Fig. 18.

Fig. 18 Relation between DAS and mechanical properties of Al-7Si-0.4Mg alloy^[1]

The author has proposed the view that the fall in elongation with increasing DAS is the result of the unfurling of bifilms.^[1] If the melt is solidified quickly the bifilms are frozen in as compact, and therefore small and relatively harmless defects, as described above. Conversely, if freezing occurs over a long time interval the unfurling process of more bifilms can progress further towards completion. Thus, after a long solidification time the metal is now filled with large cracklike defects, so that the ductility is impaired. Clearly, the DAS, being controlled by a coarsening process, in turn controlled by the diffusion of solutes in the liquid, simply increases as time progresses, and so is the indicator of the time available for unfurling. DAS is not the cause of the fall in elongation, it is merely the independent clock that monitors the passing of time.

One may speculate that for extremely clean melts of aluminium alloys the relation for elongation versus DAS would be not a decreasing curve, but a nearly horizontal line. Any residual small downward tendency would be the true effect of the metallurgical microstructure.

FRACTURE

The Central Role of Entrained Defects

Brittle failure appears to be accurately described using some variant of the Griffith crack concept, in which the rate of release of the elastic energy built up in the material exceeds the energy to propagate a pre-existing crack.

Where there is no pre-existing defect, however, fracture seems unlikely for the following reasons. For pure liquid metals, the theoretical fracture stress is quickly estimated from the well known equation for the equilibrium pressure difference ΔP across a curved surface of radius r

$$\Delta P = 2\gamma / r$$

The surface tension γ for liquid Fe is in the region of 2 N m^{-1} . Assuming an embryonic nucleus of approximately 2 atomic diameters, giving a bubble volume of approximately 8 atomic volumes, ΔP is of the order of 10 GPa.

Similarly for solid Fe, assuming a surface energy of around 2 J m^{-2} , if 1 m^2 of atoms were separated to form a uniform crack of thickness one atomic radius, approximately 0.1 nm, the stress to achieve this would be 10 GPa. Thus the strengths of both liquid and solid phases are similar. This is to be expected because the interatomic distances in both are similar.

It is clear therefore that the stresses required to separate atoms in the solid are so great that it is not expected that bonds could normally be broken. The supposition that such events as dislocation pileups or other micromechanisms would cause cracks is therefore curiously illogical; in most metals the huge stresses involved would first have promoted stress relieving processes such as plastic flow.

This is especially true for solids at temperatures near their melting point, where extensive plastic flow can occur easily. (However, of course, cracks might be formed in this way in materials of high intrinsic brittleness such as those with large Burgers vector.)

It follows that, as is correctly conceptualised by the Griffith crack model, only a solid or liquid phase containing a defect can fracture. Thus, for instance, an inclusion or second phase particle precipitated in a solid matrix that has nucleated, and grown by diffusion of solutes, will be incapable of creating a crack. Either the inclusion or the matrix will yield plastically, but a cavity or crack cannot open.

Interestingly, there has been evidence against the possibility of atomic sized defects opening in fcc metals since the earliest years of the TEM. Lattice vacancies were observed to condense not as spherical bubbles, or cracks, or any other volume defect, but as collapsed dislocation rings, or as stacking fault tetrahedra.^[31] (The situation with irradiation damage is rather different. Here the damage is extreme and there is often the presence of vast quantities of hydrogen in supersaturated solution.) Thus, in general, interatomic bonds are clearly so strong as to resist the opening of a major defect; the strength of the bonds forces the lattice to collapse inwards upon itself. It seems safe to assume therefore that cracks cannot occur in fcc metals from atomic processes such as dislocation mechanisms or vacancy condensation. (However, this conclusion may be safe only for pure metals. With increased alloying to strengthen the lattice, cracks might become possible.)

Thus it seems that we can conclude, with some reservation at this stage, that the formation of cracks or other volume defects in many, if not all, metals is extremely difficult, if not impossible. We are led back to the insightful Griffiths model. The defect has to preexist, and it has to be sufficiently large to have any significant or observable effect. Thus we need macroscopic defects for solids or liquids to fail. Such macroscopic defects will not include the interfaces of second phase particles precipitated from solution, nor will they include grain boundaries. Such interfaces are essentially in atomic contact (even if not closely packed as a result of some degree of local lattice disorder).

However, of course, it is widely known that solids often appear to fail from inclusions, second phase particles or grain boundaries. There are many examples, including the opening of grain boundaries in creep in such materials as Ni base superalloys, and in super-plastic forming in Al-Zn alloys. It follows that these metallurgical features cannot have been the origin of the failures, but must be associated with other, less visible, defects, and in particular, defects that already possessed non-bonded interfaces.

As discussed here, such interfaces cannot occur as a result of metallurgical reactions, and are not to be expected as a result of mechanical strain alone.

Macroscopic unbonded surfaces probably only occur by entrainment from the liquid surface during the early

processing of the metal. The three types of entrainment defects all include the surface film, but appear in various forms:

- i. film folded onto itself (bifilm)
- ii. enfolding air (bubble)
- iii. enfolding extraneous debris (exogenous inclusion)

All these defects have a high probability of surviving solidification, and would be expected to survive significant mechanical working, to act as cracks in the solid. However, they will usually be invisible to casual inspection.

Thus, in summary, failure is not expected to occur from any inclusion or other feature that has grown within the metal, whether in the liquid or solid phase, because its boundaries will be expected to be in more or less perfect atomic contact with the matrix, giving such interfaces great tensile strength. Conversely, failure is to be expected from entrained features from those liquid metals that have a solid surface film. These features are necessarily associated with an unbonded interface dragged in to the matrix from the liquid surface.

This conclusion was demonstrated by Emamy and Campbell.^[32] They compared the bonding between second phases and the Al matrix in two commercial metal matrix composites (MMC). The composite containing SiC particles introduced through the surface of the liquid alloy (as in Fig. 7), albeit claimed to be in a high vacuum environment, was observed to decohere easily under hydrostatic tension provided by natural shrinkage in a casting, creating a fine dispersion of fine pores. In contrast, the MMC containing TiB₂ particles, introduced via diffusion into the liquid alloy from a molten salt, were resistant to decoherence from the matrix. The casting made from this material remained sound despite the application of hydrostatic tension during freezing.

Ductile Fracture

It is known, and nicely described originally by Cottrell^[33] and more recently by Knott,^[34] that ductile failure occurs by plastic strain around second phase particles causing cracking of the particles or the debonding of the particles from the matrix; the voids then linking to produce failure.

However, once again, if we consider a matrix with second phase particles that has formed from the liquid state, perfect atomic bonding, and essentially defect free particles, can be expected since they will have formed atom by atom. Thus neither cracking nor debonding would be expected. This conclusion is reinforced by such studies as that by Ward *et al.*,^[35] who studied nanoparticles of Si in an Al matrix by molecular dynamic techniques. They found the bond strength between the particle and the matrix to be approximately 8 to 10 GPa, and the particle itself to be even stronger since it resists failure at the decohesion stress. Thus failure from these interfaces in mutual atomic contact is not to be expected in any normal metallurgical condition.

The fact that, in practice, cracking of Si particles is common, and debonding is commonly (but not always) observed, suggests that an unbonded variety of defect must be present. Since it is known that bifilms are common in Al alloys, and since it is also known that Si particles preferentially nucleate and grow on such defects, so that they would be preferentially incorporated into growing Si particles, it does not seem an unreasonable step to put these facts together. It follows that ductile failure by cracking and debonding events in second phase particles is likely to be the result of the presence of bifilm defects inside and occasionally on the surface (if the particle forms only on one side of the bifilm, as is to be expected on occasions) of the second phase particles.

It seems therefore that bifilms may be in action in many if not most fractures. In an Al alloy fractured intermetallics are found to sit at the base of ductile dimples. From current evidence it seems that the intermetallics almost certainly all formed on bifilms and were therefore pre-cracked throughout their volume. Without the bifilm the intermetallic, if it existed, would almost certainly not crack. More probably it would not have formed at all; its components continuing to remain in solution in the matrix in the absence of a suitable substrate on which to deposit. If the inter-metallic had formed in some way in the absence of the bifilm, the excellent atomic bonding with the matrix would ensure that the ductile failure of the matrix would probably proceed to a full 100% reduction in area (allowing for the volume percentage of non-deformable particles). These conjectures require to be confirmed.

Nevertheless, the current evidence is persuasive. In commercial Al casting operations over the past decade or so, and more especially in recent years, the rise in elongation to failure values from around 0 to 1%, then to 10% and recently to 20% is already happening by paying attention to the handling of the liquid metal and its quality.

It seems only a matter of time before elongations similar to those of steels, in the region of 40 to 50%, are achieved in cast Al alloys. Perhaps the values for steels are also limited by bifilms, so that both Al alloys and steels should actually achieve nearer to 100%. For such high values of ductility it seems more rational that we should be making use of the reduction in area (RA) measure. It is predicted that we should achieve 100% RA for bifilm free material.

WROUGHT MATERIAL

Wrought material has conventionally been thought of as sound because the working process has been assumed to weld closed most if not all casting defects. It may be true that this occurs in some alloys. For those metals and alloys with strong, stable surface films, however, there is plenty of evidence that entrainment defects survive even severe working processes.

In the solid state the bifilm frozen into the solid billet will be expected to retain residual air in folds and trapped microbubbles. Thus during a working process the elongation of the defect would be accompanied by the simultaneous oxidation (or nitridation) of its newly created surface, so that bonding would be resisted. The area of the bifilm would require to be extended greatly before the residual air was consumed, so that only further extension beyond this stage would result in the formation of a bond. Thus during working, properties would be expected to get worse before they get better. This certainly seems true of the practical experience of those who work in the production of Al alloy forgings, where the forging process effectively confers so little work that the casting defect is merely pushed around a little, but is substantially unchanged.

The longevity of bifilm defects is nowhere better seen to advantage than in Al alloy extrusions. Filiform corrosion most clearly reveals the impressive density of these defects on the surface of the extrusion. The action of bifilms in the enhancement of corrosion is described more fully later.

In a wrought material the bifilm would be expected to have found its way to a grain boundary during the one or more recrystallisation events, since the grains would not be able to grow through the boundary, and would therefore find their boundaries becoming fixed; coexistent with a bifilm. The interesting microstructures showing differences between individual grains in the rate of grain growth as a result of some boundaries being clearly fixed whilst others are free to move at speed should, perhaps, be expected. Naturally, this will be expected to have a significant effect on the development of grain textures during working and recrystallisation, and holds the promise of integration of bifilm concepts with traditional texture analysis.

CORROSION PROPERTIES

The effect of bifilms on the corrosion of metals is perhaps one of the more surprising consequences of surface turbulence during casting.

When a metal is subjected to a corrodant, the attacking fluid will naturally seek out the bifilms that connect to the surface of the material. The bifilm acts as a channel to permit the corrodant to penetrate deep into the interior of the metal, greatly accelerating the severity of the attack.

Furthermore, the role of the bifilm in corrosion is expected to be greatly amplified by the presence of its associated intermetallics. This is particularly true for Al alloys in which the common precipitates on bifilms are a phase rich in iron (for instance the beta-iron rich phase Al_3SiFe) or copper ($CuAl_2$). Both these intermetallics form highly effective corrosion couples in conjunction with the Al matrix. Other candidate matrices and precipitate combinations are listed in Table 1. Although, of course, the intermetallics are precipitated on the underside of the oxide film, the film is of course often only a few

molecules thick, and probably contains multiple fractures after solidification and cooling, and possibly after a working process. Thus there is little hindrance in the form of an insulating oxide barrier to prevent the corrosion couple from operating efficiently.

Filiform corrosion in rolled or extruded aluminium alloys is perhaps the best and clearest example of the vast scale, ubiquity and density of defects inherited from casting in present day engineering materials. The subject is dealt with in greater detail elsewhere.^[1] Briefly, filiform corrosion can be assessed in a laboratory test on a rolled or extruded plate of alloy that might have been protected by, for instance, a layer of paint. A scratch across the paint layer, usually made at right angles to the working direction, extending into the metal beneath, is subjected to corrosive conditions such as a salt spray. Corrosion is then observed to progress from the scratch, in lines or filaments parallel to the working direction. The filaments progress partly along the surface, the corrosion products slightly lifting the paint layer. In their linear progress the filaments occasionally dive beneath the metal surface, only to emerge once again a little later. The lengths of the filaments are typically in the range 1 to 10 mm, the length to be expected from bifilms originally in the range of diameters 0.1 to 1 mm in DC cast alloys. Eventually, the filaments spread sideways to join up, undermining the whole paint or other protective layer.

The number of sites of attack reveals the extent of the defect problem. Thus in filiform corrosion the number of filaments, or in pitting corrosion the number of pits, becomes the clear indicator of the number of casting defects. Multiple filaments and pits per square millimetre are common, and correspond well with the expected numbers of bifilms. (In the absence of bifilms, a spectrum of lesser defects may act to encourage pitting. Ultimately, dislocations achieve this role in some materials. However, the scale of pitting corrosion in such cases is greatly reduced of course.)

The central role of the bifilm in corrosion has been proposed by Mahta and co-workers^[36] in careful experiments in which they studied the corrosion of sacrificial anodes cast from an Al–Zn–Sb alloy. They found that even though the alloy was within its chemical specification, and had the optimum grain refined structure, uniform and thus efficient corrosion could not be guaranteed. Only if bifilms were present in high number density was uniform dissolution observed. If excessive grain refining elements Ti and/or Zr were added to the melt, the excess elements would precipitate on bifilms, causing them to sink to the bottom of the casting ladle. (Such precipitation of grain refiners together with oxides in melting and holding furnaces is well known to be a common feature of all aluminium alloy casting operations, constituting the sludge that needs to be cleaned out of the furnaces regularly.) In this way the melt was largely cleaned from bifilms before casting, resulting in an uneven distribution of the few remaining bifilms, and thus a non-uniform dissolution of the alloy.

It is proposed that corrosion filaments and pits may be initiated only on casting defects. If true, highly significant increases in the corrosion resistance of many materials could, in principle, be achieved simply by introducing improved melt control and improved casting technique to avoid entrained unbonded interfaces in metals, onto which corrosion couple intermetallics precipitate, and into which corrodants can enter. At the present time the bifilm, present in profusion, has all those features necessary, and all colocated, to ensure maximum efficiency of corrosion. It is fascinating to speculate that by attention to the detail of the casting operation we may eliminate a number of important corrosion problems in metals.

THE HEALING OF BIFILMS

It is understandable that bifilms and other unbonded interfaces in entrainment defects will be closed by the application of external pressure. Closure, of course, does not necessarily include bonding so as to cause the bifilm to weld shut. Even so, closing will confer some strength as has been discussed above regarding the arguments concerning pores and bifilms.

Given time, the bifilm was predicted by Nyahumwa and colleagues to consume all its internal oxygen and nitrogen, and thus gradually close.^[28] This prediction has been recently verified by Raiszadeh and Griffiths^[37] by monitoring the rate of consumption of oxygen and nitrogen in air bubbles trapped beneath liquid aluminium. Raiszadeh found that for a typical bifilm its internal air could be consumed within times in the region of a few seconds or minutes. This may explain why it has appeared that old bifilms in suspension in melts seem to be less damaging to mechanical properties than bifilms introduced to the casting by turbulence in the mould cavity itself. Even so, these very short times calculated for perfect parallel films may be greatly lengthened by irregularly folded films that will contain additional reservoirs of air in folds and microbubbles.

This process can of course be encouraged and accelerated by the application of pressure to the casting. Pressure applied immediately after casting, prior to solidification, has been demonstrated many times to be beneficial to mechanical properties.^[38] Similarly, in the solid state, the mechanism of hot isostatic pressing (hipping) can be easily understood to increase mechanical properties.

The bonding across the internal bifilm interface, however, is a separate matter. In Al alloys for instance, those containing extremely low levels of Mg exhibit an alumina film, which is so stable that no bonding can be predicted. Similarly, those alloys containing more than about 1.0 wt-%Mg exhibit a pure magnesia film, which is similarly inert. However, intermediate alloys, of which the important and widely used Al-7Si-0.4Mg alloy is one, appear first to form an alumina film that slowly converts

to a spinel, the mixed oxide. During this conversion, the atomic rearrangements might allow a certain amount of diffusion bonding, assisting the bifilms to heal by eliminating their cracklike nature. At higher temperatures, for instance in the case of steels, hipping is expected to result in more favourable sealing behaviour.

PERSPECTIVES

Bifilms promise to be a fruitful source of new insights into the behaviour of metals. Their influence appears to be wide ranging throughout metallurgy, as this short account attempts to illustrate. The panorama includes.

Cast Metals

The history of the bifilm, its origin and its transformation into the astonishingly wide spectrum of familiar casting defects is summarised in Table 2. There is a compelling logic to the history of evolution of the bifilm into its various manifestations when reading the table from left to right, appearing to present the explanation of every one of our familiar casting defects. Table 2 outlines predictions based on the hypothesis that defects cannot occur in liquid metals, nor in solidifying metals, and possibly not even in solid metals, without the presence of the prior existence of entrainment defects. All the internal defects in cast materials are hypothesised to occur from remnants of the entrained surface. The character of the entrained surface varies enormously, giving the wide spectrum of responses. It follows that metals without bifilms will be expected to exhibit no defects. The laboratory and industrial evidence for the truth of this profound summary is growing ever more convincing.

Table 2 dictates a rethink of our classical theories of the formation of structure in cast metals. (For instance it is well known that grain size is often controlled by dendrite multiplication, in turn controlled by convection. However, it seems that convection is commonly controlled by the purely mechanical blocking of flow in conditions of a high density of bifilms, creating large grains irrespective of conditions for constitutional undercooling or the presence of added nuclei.)

Failure Analysis

Furthermore, many metals that currently exhibit brittle failure may only do so because of their high content of bifilms. (The analogy of steel versus cast iron, whose brittle behaviour is the result of its dense array of graphite films, is mirrored in the comparison of well cast steel versus poorly cast aluminium alloys, whose poor ductility is the result of a dense array of bifilms.)

Similarly, grain boundary failure in ductile failure, creep and superplastic forming all appear logical

Table 2 Entrainment defect histories

Entrainment		Quiescence			
Entrained surface	Compaction of defect	Liquid at rest	Solidification		Casting defect
			Unfurling	Inflating	
Film free	Coalesced matrix liquid	Rapid flotation of bubbles			None
Liquid film	Coalesced droplets of surface liquid	Rapid flotation of large droplets			Few defects (residual small drops)
Partially solid film	Furled bifilm partly welded closed	Rapid flotation of compact bifilms			Large macro-inclusions on cope surface of casting
Solid film	Buoyant bubbles Furled bifilms	Rapid flotation Slow flotation or suspension resulting in widely distributed defects. Suppression of convective flow Isolation of local volumes	Uniaxial strain Dendrite pushing Crystal pptn Gas pptn Hydrostatic strain	Inflating Further gas pptn Further hydrostatic strain	Air bubbles, bubble trails Hot tears, cold cracks Interdendritic and grain boundary cracks and hot tears. Crystal centerline or matrix 'decohesion' cracks Gas micro-porosity Shrinkage porosity Large grains Random undercoolings

candidates for explanation, and await confirmation by critical experiment. It has already been demonstrated that the reduction in the density of bifilms in Al alloys can increase the fatigue life by up to 100 times.

Macrostructure and Microstructure Development

The presence of bifilms has been shown to greatly influence the growth of grains during solidification. In the solid state, grain growth and the development of texture during working would also be expected to be significantly affected.

Corrosion of Metals

Corrosion pits and corrosion filaments occur principally, if not exclusively, on entrained casting defects. Thus much troublesome metallic corrosion could in principle be eliminated by good casting practice.

Deactivation of Bifilms

Bifilms can be closed by the application of pressure applied in the liquid or solid state, with benefits to mechanical properties. The rebonding across the internal bifilm interface remains more difficult, however, and if possible at all, takes time, but may add further to properties. Deactivation

remains, however, an expensive second best to the avoidance of entrainment by the implementation of improved casting technology.

ACKNOWLEDGEMENTS

The author is grateful to his many students and colleagues who have shared the excitement of this journey to discover the existence and nature of a defect that, ultimately, has seemed only a matter of commonsense.

Extractive Metallurgy of Aluminum

Fathi Habashi

Laval University, Quebec City, Canada

Abstract

Aluminum comprises 8% of the earth's crust and is the most abundant structural metal. Its production has surpassed that of copper and approaches that of iron. This article is a review of all aspects of the production of aluminum including: the raw materials from which it derived, production of aluminum from bauxite, electrolytic reduction of aluminum oxide, purification and refining, and environmental aspects of production processes.

Keywords: Bauxite; Calcination; Cryolite; Electrolytic reduction; Refining.

HISTORY

Since Humphry Davy announced in 1808 his belief that the plentiful compound alumina was the earth (oxide) of an undiscovered metal, scientists had been making efforts to obtain this new metal. Davy never made any aluminum himself; but in 1825, the Danish scientist Hans Christian Oersted (1777–1851) published his successful experiment in producing a tiny sample of the metal in the laboratory by reducing aluminum chloride with potassium amalgam. Potassium was isolated a few years earlier by Davy.

Two years later, Friedrich Wohler (1800–1882) in Germany produced tiny globules of aluminum by the same method, and was able to demonstrate the metal's lightweight and malleability. Henri Sainte-Claire Deville (Fig. 1) in France in 1854 showed that cheaper sodium could also be used, and the first commercial plant producing small quantities of aluminum was begun in 1855. Since potassium and sodium were produced electrolytically, the process was expensive.

In 1886, following the development of large-scale equipment for generating electrical power, Paul Heroult (Fig. 2a) in France, and Charles Hall (Fig. 2b) in the United States, independently developed a process for the direct electrolytic decomposition of Al_2O_3 . They discovered that when an electric current is passed through molten cryolite containing dissolved Al_2O_3 at 980–1000°C, molten aluminium is deposited at the cathode and carbon dioxide is liberated at the carbon anode. This discovery, coupled with the process developed by Karl Josef Bayer (Fig. 3) in 1888 for the production of alumina, resulted in the modern process for the production of aluminum.

GENERAL REMARKS

Aluminum comprises 8% of the earth's crust and is, therefore, the most abundant structural metal. Its production

since 1965 has surpassed that of copper and now comes next to iron (Fig. 4). Its unit price started very high and today is comparable to copper (Fig. 5). It is competing with copper in the electric industry and as a material of construction. Although the electrical conductivity of aluminum is slightly lower than that of copper, it is still economical to use in preference to copper in power cables because of its lighter weight. As a material of construction, aluminum can be anodized to get a protective oxide film, which can be dyed to give a colorful appearance. For the production of the metal, the following points should be taken into consideration:

- The electrowinning of aluminum from an aqueous solution is not possible because of the strongly negative deposition potential of this metal and the rapid hydrolysis of the aluminum ion.
- Oxides in general have high melting points. Therefore, for the electro-winning of aluminum from its oxide, a suitable low melting point electrolyte must be found in which the oxide is appreciably soluble.
- In the manufacture of aluminum, there are two main stages. The first embraces the production of pure Al_2O_3 from bauxite, and the second is the reduction of this Al_2O_3 to the metal in a bath of fused cryolite (Fig. 6).
- In the electrowinning of aluminum from oxide melts, the carbon anodes are quantitatively consumed.
- The production of alumina from bauxite is the largest pressure leaching operation in the world.
- Similarly, the production of aluminum by the molten salt electrolysis of alumina in cryolite is the most important industrial application of molten salt electrowinning and is the largest electrolytic industry in the world.
- The electrolytic step in aluminum production is the most energy intensive operation (Table 1).

Al ₂ O ₃ production	22.3
Metal production	73.1
Total	100.0

- Material handling is a major cost factor in aluminum production. For each ton of aluminum produced, more than 3 tons of materials are transported to and from potlines.
- The electrolytic process produces aluminum with purity as great as 99.5–99.8%. Higher purity (99.99%) is obtained by an electrolytic refining process.

RAW MATERIALS

The production of aluminum by fused salt electrolysis takes place in an electrolytic cell which consists of a carbon

anode, a molten cryolite–alumina electrolyte, a pool of liquid aluminum, and a carbon-lined container to hold the metal and electrolyte. Fresh alumina is added from time to time and the metal formed is siphoned out periodically. The reactions taking place can be simplified as follows:

Aluminum Oxide

Almost all the alumina feed is made from bauxite which contains about 50% Al₂O₃ in the form of hydroxides of aluminum. The ore is digested with caustic soda solution under pressure to dissolve the alumina as aluminate leaving behind a red mud containing iron oxides and other major impurities. At the same time, sodium aluminum silicate should also be brought down onto the mud to minimize the silica content of the liquor; otherwise, the final aluminum hydroxide is contaminated. The aluminate solution is then seeded with crystals of hydroxide to deposit this material in a form that is easily washed and handled. The precipitation is performed in cycles leaving behind a large quantity of crystals to seed the next cycle. Finally, the hydroxide is calcined to alumina at 1200°C to give a product >99% pure. To produce 1 ton of aluminum, about 2 tons of Al₂O₃ are required.

Russia is the only country producing Al₂O₃ from sources other than bauxite. Lacking large, commercially viable bauxite reserves, the former USSR has pioneered the production of alumina from nepheline, alunites, kaolin, shale, ash, and other alkali-free aluminosilicates, which

are plentiful in the country. Production techniques developed in the former USSR are used at the Volkovsky and Pikalevsky aluminum plants near Saint Petersburg and at the Achinsk alumina complex in Siberia. In producing alumina from nepheline, the only other raw material required is limestone. Four tons of nepheline are heated in rotary kilns with 12 tons of limestone to produce 1 ton of Al_2O_3 , 0.7 ton of Na_2CO_3 , 0.3 ton of K_2CO_3 , and variable amounts of portland cement.

Carbon

Carbon is used for fabricating the anodes as well as the cathodes. It is a major item in making aluminum.

- Anodes are consumed in amounts of 0.4–0.5 kg of carbon/kg of aluminum produced; the theoretical consumption is 0.33 kg/kg Al. Since the ash from the carbon will contaminate either the aluminum produced or the electrolyte, high-purity carbon is desirable. The coke residue from petroleum refining has been the major source of carbon for anodes. This coke, produced at about 500°C, requires calcining at 1200°C to remove volatile constituents and increase its density.
- Cathodes are consumed in amounts of 0.02–0.04 kg of carbon/kg of aluminum produced due to disintegration during electrolysis. The cathodes are usually made of anthracite. Purity requirement is not as strict as in the anodes since contamination of the metal from the cathodes is negligible.

Cryolite

Cryolite has been found only in Greenland. It was mined there in the early 20th century and is now exhausted. Synthetic cryolite is produced by reacting hydrofluoric acid with alkaline sodium aluminate solution:

Some cryolite is produced directly in reduction cells by reaction of the soda impurity in the alumina with added aluminum fluoride:

In modern plants with equipment for fume treatment, cryolite is a by-product rather than a raw material.

Fluorides

Although cryolite is not consumed during electrolysis, there are some losses due to volatilization as HF and different fluorine compounds estimated at 3–5% of the metal produced. Some of these are captured and returned to the cell, others are lost. Many aluminum reduction plants have facilities to produce the hydrofluoric acid necessary for preparing cryolite and other additives as AlF_3 , LiF, and MgF_2 . Hydrofluoric acid is prepared by reacting fluor spar with concentrated H_2SO_4 :

ALUMINUM OXIDE FROM BAUXITE

Bauxite,* named after the village *Les Beaux* near Marseille in southern France where it was first discovered, is not a mineral, but designates various kinds of aluminum ores consisting mainly of aluminum hydroxide. Three aluminum hydroxide minerals occur in bauxite: gibbsite, bohmite, and diaspore. They differ considerably in their physical properties, as shown in Table 2. A bauxite deposit consists mainly of either one of these types, although cases are known when mixed hydroxides are present in one ore. Bauxites vary in color from cream to dark brown when the iron content is high. Table 3 shows the composition of a typical bauxite. The main occurrences of bauxites are

in Jamaica, Suriname, Ghana, Sierra Leone, Australia, Russia, and Hungary.

The treatment of bauxite to produce pure Al(OH)₃ from which pure alumina is obtained by the Bayer process using sodium hydroxide solution is the oldest and the largest pressure leaching operation in terms of the tonnage of raw material treated (Fig. 7). Aluminum minerals in bauxite are soluble in dilute H₂SO₄ but this acid is not used in large scale for the following reasons:

- Iron minerals and to some extent titanium minerals are also soluble; this will lead to an excessive reagent consumption and solution purification problem later.
- Al(OH)₃ precipitated from acid solutions is gelatinous and difficult to filter and wash.

Acid leaching is used only on a small scale to produce aluminum sulfate which is needed for water treatment.

The use of sodium hydroxide to leach bauxite was invented in 1892 by Karl Josef Bayer as a process for obtaining pure aluminum hydroxide which can be calcined to pure Al₂O₃ suitable for processing to metal. The process involves three steps: selective dissolution of aluminum hydroxide from bauxite, precipitation of pure aluminum hydroxide from the solution, and calcination of the hydroxide to Al₂O₃. Historically, the precipitation step was invented before the leaching step.

Leaching of Bauxite

About 90 million tons of bauxite are treated annually by this process. About 2 tons of bauxite yield 1 ton of Al₂O₃ from which 0.5 ton aluminum is produced. Also, 2 tons of bauxite produce 1 ton of waste minerals called *red mud*. Crushed bauxite is usually washed to remove fine particles of clay, dried in a rotary kiln, then ground to 60–100 mesh; the drying process is essential to facilitate grinding. Drying temperature should be less than the temperature of dehydration of aluminum hydroxides; otherwise, the solubility will be impaired. Figure 8 shows a flowsheet of the process and Fig. 9 shows an operating plant. The reactions in leaching are the following:

Leaching is usually carried out in mild-steel autoclaves, with direct steam injection for heating and agitation (Fig. 10). Operating conditions depend on the type of minerals in the bauxite. Bauxites containing gibbsite are leached at a lower temperature, with lower NaOH concentration, and for a shorter time than those containing bohmite and diasporite as shown in Table 4. The more concentrated the NaOH, the faster the rate; however, highly concentrated solutions will require excessive dilution in the later stage of precipitation, which presents difficulties in handling and filtration. Therefore, there must be an optimum concentration which compromises between digestion time and subsequent operations.

Leaching time could be shortened to 3–4 min if the process is conducted in tube autoclaves at 330°C and 25,000 kPa; also, the settling properties of the mud are improved. In tube autoclaves (Fig. 11), the slurry is pumped into an externally heated thick-walled tube about 30 cm in

**Fig. 7** Annual processing of bauxite worldwide

Fig. 8 Flowsheet of the Bayer process

Fig. 9 Bauxite treatment plant by the Bayer process in Kwinana near Perth in Australia produces 1,250,000 tons/year alumina (ALCOA)

diameter and 30–50 m long. The major part of the heat is supplied by the slurry leaving the tube. Only at the extreme end of the tube, steam from an outside source is used for heating.

Sometimes, NaOH is formed in situ in the autoclaves by adding sodium carbonate and calcium hydroxide:

To a leach solution containing 200–250 g/l Na_2CO_3 , enough lime is added such that the solution contains about 140 g/l NaOH. Leaching is carried out at 140°C for about 1 hr. This method applies only to gibbsite, because in the case of böhmite or diaspor, a sodium hydroxide concentration

Fig. 10 A typical autoclave for leaching bauxite

Table 4 Typical leaching conditions of bauxite with NaOH

Ore	Temperature (°C)	Pressure (kPa)	NaOH (g/l)	Time (hr)
Gibbsite	140	400	140	1
Böhmite	180	800	350–600	2–4
Diaspore	180	800	350–600	2–4

above that which can be obtained directly from Na_2CO_3 and lime is required. So, it is necessary to prepare NaOH separately and concentrate it by evaporation for use in leaching.

Fig. 11 Tube autoclaves used mainly in Germany for leaching bauxite

Behavior of Impurities during Leaching

Depending on their chemical properties, impurities in the ore may be found either in solution, or in the insoluble residue. Impurities that go into solution are either redeposited during a later operation, or remain in the mother liquor during crystallization of aluminum hydroxide. However, due to recycling, they will accumulate in solution and would contaminate the product. Certain tolerable levels are, therefore, maintained by bleeding the solution at regular intervals. Table 5 shows the distribution of impurities during the processing of bauxite, and Table 6 shows the composition of the leach solution. Essentially, the Bayer process eliminates the three major impurities in bauxite Fe_2O_3 , SiO_2 , and TiO_2 . Calcium and magnesium are mainly present as dolomite and are not dissolved. Apatite is partially soluble and is usually eliminated during leaching by adding $\text{Ca}(\text{OH})_2$.

Organic Matter Most bauxites contain about 0.1% organic matter. During digestion, some of this material is dissolved, causing the liquors to darken, while the remaining part is degraded and oxidized to oxalates. Some of the organic matter is, therefore, responsible for NaOH losses. Their presence may also cause liquors to froth, or may interfere with the subsequent process of hydroxide precipitation, or color the hydroxide. It may be largely eliminated during digestion by adding an oxidizing agent, e.g., MnO_2 . In some cases, sodium oxalate is crystallized and removed.

Table 5 Distribution of impurities during the processing of bauxite

	Bauxite (%)	Red Mud (dried at 105°C) (%)	Calcined Al ₂ O ₃ (%)
Al ₂ O ₃	57.8	14.0	99.55
SiO ₂	3.5	7.6	0.05
Fe ₂ O ₃	24.3	57.6	0.04
TiO ₂	2.5	5.7	—
Na ₂ O	—	7.4	0.18
Loss on ignition	12.5	7.7	0.18

Table 6 Composition of typical aluminate solution
g/100 g free Na₂O

Al ₂ O ₃	32.80 ^a	Cl ⁻	1.00
CaO	0.12	CO ₂	3.74
Fe ₂ O ₃	0.05	F ⁻	0.03
Ga ₂ O ₃	0.22	MgO	0.17
Na ₂ O	100.00	P ₂ O ₅	0.90
SiO ₂	0.60	SO ₃	0.07
TiO ₂	Trace	V ₂ O ₅	0.45

^aIn the precipitation step, about 2/3 of the aluminum in solution is precipitated.

It should be noted, however, that the organic matter in the liquor may come from the flocculants added to assist the mud to settle.

Iron Iron occurs in bauxite mainly as hematite, Fe₂O₃, and is not attacked by the caustic leaching. Thus, the residue remaining after leaching has a high percentage of iron oxides, and, therefore, has a red color. That is why this residue is usually referred to as red mud. However, some ores contain ferrous iron in the form of siderite, FeCO₃. This is attacked by NaOH, forming colloidal ferrous hydroxide:

which is difficult to settle. It would, therefore, be advantageous to oxidize ferrous minerals to ferric during leaching.

Silicon Silicon occurs as quartz, SiO₂, or as clays, e.g., kaolinite, Al₂(OH)₄(Si₂O₅). Quartz is insoluble in NaOH under the conditions of leaching but the silicates are soluble. During digestion, silica that goes into solution combines with alumina and sodium hydroxide forming insoluble hydrated aluminosilicates such as 2Na₂O·2Al₂O₃·3SiO₂·2H₂O, which are carried away in the red mud, thus causing losses. About 1 kg of NaOH is lost for each kilogram of soluble silica in bauxite. Although most of the soluble silica in bauxite is precipitated during digestion by forming sodium aluminosilicate, small amounts may still

be found in solution, especially when concentrated NaOH solution is used. To precipitate the silica completely, addition of CaO is recommended, since insoluble calcium silicate can be formed. Lime addition during digestion has a further advantage: any Na₂CO₃ present in the solution due to absorption of CO₂ from the atmosphere, and which has no dissolving action on bauxite, will be converted to NaOH.

Gallium Gallium occurs in most bauxites, and is highest in French bauxites (0.0–0.05% Ga₂O₃). It dissolves completely during extraction. Recycling of NaOH in the process results in gallium enrichment up to 0.5 g/l. Such liquors are, therefore, an important source of gallium, from which it can be recovered, e.g., by solvent extraction or by electrolysis using a mercury cathode. If, however, gallium is not recovered and is left to build up in the leach liquor, it will reach a certain concentration beyond which it will be partially deposited, together with aluminum hydroxide during precipitation, thus causing contamination.

Vanadium Vanadium in bauxite is partly soluble during digestion. In some ores, it is precipitated during evaporating the leach solution as complex salts such as 2Na₃VO₄·NaF·19H₂O. This is especially the case for ores containing fluorine since fluorides are dissolved during leaching. Sometimes, these precipitate to form a hard scale in the evaporators which interferes with heat transfer. In other ores, vanadium builds up in the recycled NaOH to a concentration of about 0.5 g/l V₂O₅ and is recovered.

Mechanism of Dissolution

Because of their slightly ionic character, aluminum hydroxides in bauxite form minor amounts of ions when added to water. For example:

The value of the equilibrium constant is very small. Equilibrium is disrupted when the concentration of any of the ions Al^{3+} or OH^{-} is decreased; thus, more solid will go into solution to keep the value of K constant. Decreasing any of these ions may be the result of a neutralization reaction or a complex formation. In the presence of an acid, the OH^{-} ions are neutralized:

This shifts the equilibrium to the right and more hydroxide goes into solution:

Aluminum hydroxide is an amphoteric hydroxide, i.e., it may behave as an acid:

In the presence of an alkali, the H^{+} ions are neutralized:

The equilibrium is shifted to the right and more hydroxide dissolves:

Thus, aluminum hydroxide is soluble in both acid and alkali.

Engineering Aspects

High-pressure membrane piston pumps (Fig. 12) are used for introducing pulps into autoclaves. Flash evaporators are usually installed after an autoclave. These are large, vertical tanks in which the hot slurry is introduced through a tube directed towards the bottom of the tank where protective baffles are installed to minimize the erosion of the tank due to impact (Fig. 13). This equipment serves three purposes:

Fig. 12 High-pressure pump

Fig. 13 Flash tank

decreasing the pressure and temperature of the slurry, recovery of heat in the form of low-pressure steam, and concentration of the solution as a result of the flash evaporation of water. Slurries, to be introduced in an autoclave, are usually preheated by the steam generated in the flash evaporator.

Slurries obtained after leaching are then filtered to recover the leach solution, then washed to remove the entrained solution. The red mud generated is usually disposed of in ponds, and in some cases, transported by a pipeline under the sea.

Precipitation of Aluminum Hydroxide

There are a large number of aluminum hydroxides known:

- Gibbsite, $\gamma\text{-Al}(\text{OH})_3$, occurs in huge quantities in bauxite and is produced in large scale by the Bayer process by cooling slowly a concentrated solution of sodium

Fig. 14 Part of a layer of $\text{Al}(\text{OH})_3$. The heavy and light open circles represent OH groups above and below the plane of the Al atoms (shaded)

aluminate in the presence of crystal seeds. A crystalline product is obtained in the form of hexagons. The structure as revealed by x-rays emphasizes this hexagonal form. It is a layered structure composed of two planes of close-packed OH^- ions with Al^{3+} ions sandwiched between them. The Al^{3+} ions are distributed in hexagonal rings. In the interior, each Al^{3+} shares six OH^- with three other Al^{3+} , and OH^- is bridged between two Al^{3+} . Three of the six OH^- ions surrounding the Al^{3+} ion are from the upper layer, and the other three are from the lower layer (Fig. 14). Crystalline aluminum hydroxide is, thus, a giant molecule composed of layers of $\text{Al}(\text{OH})_6$ octahedra packed in a cubic form.

- Bayerite, $\alpha\text{-Al}(\text{OH})_3$, is rarely found in nature, but is prepared in a small scale when a solution of sodium aluminate is neutralized by CO_2 at room temperature at pH 9–12. If precipitation is conducted at pH above 12, gibbsite is obtained. It is similar to gibbsite but the layers of $\text{Al}(\text{OH})_6$ octahedra are packed in a hexagonal form. The Greek prefixes in this case are used systematically to differentiate between the different structures (and not for high-temperature and low-temperature modifications).
- Nordstrandite, $\text{Al}(\text{OH})_3$, is obtained by precipitating a gel from aluminum salt solution with ammonia. Upon aging under the mother liquor at pH 7.5–9, the gel is converted to the crystalline phase that became known as nordstrandite. It was also identified in some soils. Its structure is in-between that of gibbsite and bayerite.
- Diaspore, $\alpha\text{-AlOOH}$, is aluminum oxide hydroxide that occurs as a major constituent in geologically old bauxites. It is composed of chains of double molecules arranged in a nearly hexagonal close packing:

- Boehmite, $\gamma\text{-AlOOH}$, also occurs in some bauxites, and is composed similar to diaspore, but the chains are arranged in a cubic form.

When the different forms of aluminum hydroxides and oxide hydroxides are heated below 700°C , they yield alumina of high affinity to adsorb water, many organic molecules, and a number of ions from aqueous solutions. The fully dehydroxylated product, $\alpha\text{-Al}_2\text{O}_3$, is inert and is obtained by heating at about 1000°C . During this process, a number of intermediate crystalline forms are obtained. The reaction path and kinetics of dehydroxylation are influenced by the particle size, the rate of heating, the water vapor pressure in the atmosphere surrounding the solid, and the presence of trace impurities.

Gelatinous aluminum hydroxide does not have the symmetry of a crystalline hydroxide. It is composed of $\text{Al}(\text{OH})_3$ molecules agglomerated together through shared OH^- ions and hydrogen bonds, which can include intermediate water molecules. Since the hydrogen bonds are much weaker than covalent bonds, the agglomerate is soft and nonsymmetrical. Alumina is, therefore, always calcined to the α -form known as corundum, which is the most dense, hard, stable and nonreactive aluminum oxide. $\gamma\text{-Al}_2\text{O}_3$ is cubic closest packed with respect to the oxygen ions and $\alpha\text{-Al}_2\text{O}_3$ is hexagonal closest packed; aluminum ions occupy interstitial positions. The transformation of $\gamma\text{-Al}_2\text{O}_3$ to $\alpha\text{-Al}_2\text{O}_3$ is endothermic ($\Delta H = 20.6 \text{ kcal}$).

In the Bayer process for leaching bauxite, an alkaline sodium aluminate solution is obtained from which aluminum hydroxide is precipitated:

The basis of this process is obtaining a crystalline product (Fig. 15) which is easy to filter and wash, so that it is of the highest purity. To obtain a thoroughly crystalline

Fig. 15 Electron photomicrograph showing the crystalline nature of aluminum hydroxide precipitated from the alkaline solution (Bayer process). The edge of the hexagon is about 8μ and its thickness is about 4μ

Fig. 16 Precipitation tanks for aluminum hydroxide

precipitate, the aluminate solution is stirred with a large excess of aluminum hydroxide “seed”. The seed has two functions:

- It reacts with the OH^- ions, thus, shifting the above equilibrium to the right and favoring precipitation.
- It acts as a nucleus on which $\text{Al}(\text{OH})_3$ precipitates.

The solution together with a seed is left in the vessel for about 4 days (Fig. 16). Continuous agitation and cooling to $25\text{--}35^\circ\text{C}$ is necessary to permit the formation of coarsely crystalline products. A finely crystalline product is undesirable since it causes excessive dusting during calcination. In practice, the operation is conducted as follows: the slurry after precipitation is allowed to settle. The finely suspended crystals are recycled as seed, and coarsely settled crystals are withdrawn, filtered, washed, and calcined (Fig. 16). The mother liquor is evaporated, and its alkalinity is adjusted and recycled for leaching another bauxite batch.

Calcination of Aluminum Hydroxide

The final operation in the production of alumina is the calcination of the hydroxide:

The presence of moisture in alumina for use in the reduction cell for aluminum production is highly undesirable, since it leads to the formation of hydrogen fluoride. Therefore, the desired product is $\alpha\text{-Al}_2\text{O}_3$. Calcination of aluminum hydroxide is usually done in rotary kilns, and sometimes, in fluidized beds. Rotary kilns are long, horizontal, brick-lined cylinders slightly inclined to the horizontal to permit the gradual descent of solids at the upper end. They are heated by burning a carbonaceous fuel at the lower end. Aluminum hydroxide is charged to a kiln fired to about 1000°C . The solid product discharged from the other end of the kiln is then cooled in an air cooler (Fig. 17).

Fig. 17 Precipitation flowsheet

ELECTROLYTIC REDUCTION OF Al_2O_3

For the industrial aluminum production, the cathodic product is molten aluminum and the product discharged on the anode is largely CO_2 and minor amounts of CO . The overall cell reaction may be represented by:

The Electrolyte

Cryolite, the double fluoride of sodium and aluminum, Na_3AlF_6 , was found to be the best molten salt for electrolyzing Al_2O_3 for the following reasons:

- It is a good solvent of alumina.
- It has a greater decomposition potential than alumina.
- It is a good conductor.
- It can be free of metallic impurities which could be deposited.
- It has a low melting point.
- It has sufficient fluidity.
- It has a density less than that of aluminum at the working temperature.
- It has a low vapor pressure.
- It does not react with the electrodes or with the products of electrolysis.

The solubility of Al_2O_3 depends on electrolyte composition and temperature. Alumina and Na_3AlF_6 form a eutectic at 960°C with 11% Al_2O_3 . The solubility limit of Al_2O_3 at 1000°C is 13% Al_2O_3 . The solubility limit of Al_2O_3 in typical industrial electrolytes is $\approx 8\%$. For the dissolution of alumina in cryolite, the most important factor is the nature of the alumina used: the rate is faster with lower α -alumina content and larger specific area. The percentage of Al_2O_3 in the bath must be carefully controlled within narrow limits for the following reasons:

- Shortage in Al_2O_3 will cause operating difficulties – the anode effect (see later).
- Increased amount of Al_2O_3 will cause its deposition as a sludge under the metal layer. The electrolyte is agitated by:
- The bubbles of gas given off at the anodes.
- The magnetic field effect produced by the large currents passing through the anode bus bars, the cell walls, and the lining (see later).

Agitation is essential to help solubilize the alumina. Were there no agitation, the alumina would sink to the bottom of the cell and accumulate under the metal layer, thus, acting as an insulator to the cathodic carbon. However, too violent an agitation will increase the possibility of short-circuiting in the cell (anode–cathode distance decreases greatly).

The Cryolite Ratio

Aluminum fluoride is usually added to the electrolyte in excess of the Na_3AlF_6 composition. The ratio NaF/AlF_3 is called the cryolite ratio; it is 3 in pure cryolite. Although lowering the cryolite ratio can increase current efficiency of metal production, the change also increases the volatility of the electrolyte. It also adversely affects the electrical conductivity of the bath and the alumina solubility. The bath ratio is the mass ratio of NaF to AlF_3 because the molecular weight of AlF_3 is almost twice that of NaF , the cryolite ratio is double the value of bath ratio. Industrial cells operate at cryolite ratio between 2 and 3. Operating temperature is usually in the range 940 – 980°C .

The freezing point of pure cryolite is $1009 \pm 1^\circ\text{C}$, and the cryolite-10% alumina eutectic point is 962°C . The freezing points of the aluminum fluoride–sodium fluoride system are given in Fig. 18. If a direct current be passed through the solution of alumina in cryolite or alumina in cryolite plus other fluorides, the alumina will be decomposed, the aluminum being deposited at the cathode in a molten condition (melting point 660°C) and oxygen at the anode, which is carbon, with which the oxygen reacts to form CO_2 and CO . The thermal effect of the oxidation of the carbon anodes is to reduce the amount of electrical

Fig. 18 Phase diagram of the system NaF – AlF_3

Molten aluminum	2.28
Solid Al_2O_3	3–4

energy required to maintain the bath in a fused state. The bath itself is not decomposed by the current. The container is an iron box lined with carbon, referred to as a pot. The density of liquid aluminum at 950–1000°C is 2.3 g/ml (Table 7). Experience has shown the density of the molten electrolyte should be less than 2.1 g/ml to maintain good separation between the metal and fused salt phases. Additions that decrease the density of $\text{Na}_3\text{AlF}_6\text{--Al}_2\text{O}_3$ melts are beneficial.

Additives

The electrolyte contains calcium fluoride, aluminum fluoride, and sometimes, lithium fluoride or lithium carbonate to lower operating temperature and increase current efficiency. A typical electrolyte consists of 5–15% excess AlF_3 , 4–6% CaF_2 , 1–6% Al_2O_3 , and balance cryolite. Aluminum fluoride is added to:

- Neutralize the soda (about 0.6% Na_2O) present in the alumina. This results in the formation of cryolite.
- Reduce fog formation and hence increase current efficiency. However, it is consumed during operation by:
 - vaporization as sodium tetrafluoroaluminate, NaAlF_4 .
 - Depletion by hydrolysis with traces of moisture leaking to the cell:

Fluoride losses are almost completely recycled to the cells. Nevertheless, aluminum fluoride consumption amounts to 0.02–0.04 kg/kg of aluminum product. Although the

density of alumina is higher than that of cryolite, yet on the addition of alumina, the density of the cryolite melt decreases. The addition of alumina to cryolite lowers the conductivity. Table 8 summarizes the effect of the different additives on the solubility of Al_2O_3 , density, conductivity, etc. The use of additives to lower freezing points and consequently operating temperatures, is always accompanied by a reduced ability to dissolve alumina. Calcium fluoride is seldom added intentionally, because owing to a small amount of calcium oxide impurity in the alumina ($\approx 0.05\%$), it attains a steady-state concentration of 3–8% in the melt. At this level, calcium is codeposited into the aluminum.

Other additives, sometimes, used are MgF_2 , LiF , and NaCl ; all lower the freezing point of the bath which is generally advantageous, but the first two introduce possibly deleterious quantities of Mg and Li into the product and the third, by giving rise to HCl in the gas leaving the cell, generates corrosion and working-condition problems. Deleterious effects on aluminum workability restrict the lithium concentration. Since the fluorides of calcium, barium, and strontium markedly increase the specific gravity of cryolite, the amounts of these substances present must be carefully kept below a point at which the bath would become so dense that the agitation produced in it during normal operation would cause aluminum globules to float and be carried to the anode, where they would be oxidized. In practice, barium and strontium are present only in traces, and the amount of calcium fluoride is kept below 15% so as to leave an adequate margin of safety. The CaO content of the alumina should not exceed 0.04%.

Mechanism of Reduction of Al_2O_3

Cryolite is believed to be completely ionized into sodium ions and hexafluoro-aluminate ions which partially dissociates further as follows:

**Table 8** Effect of additives to electrolyte in alumina electrowinning. Downward arrow means a decrease, upward arrow an increase

	LiF	NaF	CaF_2	MgF_2	AlF_3

Density	↓	↓	↑	↑	↓
Viscosity	↓	↓	↑	↑	↓
Surface tension	↑	↑	↑	↑	↓
Electrical conductivity	↑	↑	↓	↓	↓

The high solubility of alumina in cryolite is attributed to a chemical reaction to form a complex species such as $\text{Al}_2\text{O}_2\text{F}_4^{2-}$ and $\text{Al}_2\text{OF}_6^{2-}$:

Anodic reaction:

Cathodic reactions:

Overall reaction:

According to this scheme, AlF_3 accumulates at the anode while NaF accumulates at the cathode. This was confirmed experimentally. Theoretically, oxygen depositing onto carbon at the cell operating temperature should form CO with little CO_2 :

However, based on the net carbon consumption, the anode product is essentially all CO_2 . It seems, therefore, that there is an accumulation of oxide ions at the anode so that:

The oxidation of carbon at the anode can be considered to take place according to:

where x is between 1.5 and 3.

Anode Effect

Gas generated during electrolysis is continuously discharged out of the cell. When, however, the accumulation of gas bubbles at the anode surface becomes excessive, it results in what is known as “anode effect”. It was found that the anode gas composition changes from CO_2 to CO , i.e., more carbon is consumed with significant quantities (3–25%) of CF_4 and minor amounts of C_2F_6 . This usually takes place when the bath is depleted of Al_2O_3 and hence fluoride ions are discharged at the anode together with the small amount of oxide ions generated from Al_2O_3 .

Gas accumulation at the anode causes decreased current efficiency. The molten electrolyte becomes separated from the anode which is no longer wetted. A number of small arcs are formed between the molten electrolyte and the anode, the resistance of the cell increases markedly, and in consequence, the applied electric tension rises and the current density falls. Further, as a result of the formation of electric arcs between the anode and the electrolyte, the gas film adhering to the electrode will be strongly heated, and as the gas expands the electrolyte is forced further away from the electrode. The anode effect mainly takes place in the Söderberg cell.

Current Efficiency

Theoretically, 1 kAh of electric current should produce 0.3356 kg of aluminum, but only 85–95% of this amount is obtained. The reasons for this decrease in efficiency are:

- The solubility of aluminum in the electrolyte (fogging phenomenon) which is about 0.1% in a typical industrial electrolyte. This imparts electronic conductivity to the melt, thereby lowering the current efficiency. In addition, the dissolved aluminum reacts as follows:
 - With sodium fluoride to form sodium according to:

Metallic sodium has been found in cell lining.

- With AlF_3 to form aluminum monofluoride gas according to:

- With CO_2 to form alumina:

- Reaction of molten aluminum with the cathode lining to form aluminum carbide. The current efficiency is governed by the following parameters:
 - bath temperature
 - cryolite ratio
 - anode–cathode distance
 - current density

Adjustment of the anodes for the equalization of the current passing through them is an important factor in the operation of the cell. Anodes set too low may allow projecting points to touch the metal layer in the bottom of the cell, thus short-circuiting it; anodes set too high may, because of the resistance of the thicker layer of electrolyte between them and the cathode, fail to carry their proper share of the current. The anode–cathode distance influences the diffusion of the redissolved aluminum or reducing agent towards the gaseous anodic products. It also determines the power dissipation due to electrical resistance in the electrolyte.

ENGINEERING ASPECTS OF ELECTROLYTIC REDUCTION

Cell Design

- Cells typically range 9–12 m long, 3–4 m wide, and 1–1.2 m high. Thermal insulation surrounds the carbon lining of the cell to control heat losses and is protected by a layer of frozen electrolyte called “ledge”.
- Steel collector bars in the carbon cathode conduct electric current from the cell. These bars are either inserted into holes carefully sized so that thermal expansion forms a tight electrical contact, cemented in place with a carbonaceous cement containing metal particles, or bonded in place with cast iron.
- As a result of intensive research and development in the aluminum industry in the period 1920–1990:
 - Cell production increased from 90 to about 1000 kg aluminum/day (Fig. 19).
 - Energy consumed per kilogram of aluminum decreased from 25 to nearly 12 kWh (Fig. 20).
- The molten aluminum layer is 3–25 cm thick, the electrolyte layer 15–30 cm, the anodes project through the frozen crust so that the anode–cathode distance is 4–8 cm.
- There are two types of reduction cells, based on the form of the anode: the prebaked (Fig. 21) and the self-baking (Fig. 22). Historically, the aluminum industry started with the prebaked electrode which was found to be labor-intensive because of the frequent changing of electrodes. The continuous, self-baking anode was developed by Carl W. Söderberg (Fig. 23) in Norway during World War I. Their peak period was in the 1940s and 1950s.
- The prebaked anode cell became the preferred design for two reasons:

- Development of the vibrocompacting method for producing prebaked anode blocks. This took the place of the pressing–extruding method previously used.
- Environmental problems associated with the operation of the Söderberg electrode because of the

Fig. 19 Trend in the production capacity of a single electrolytic cell for aluminum production

Fig. 20 Energy consumption/kilogram of aluminum

Fig. 21 Electrolytic cell with prebaked anodes

Fig. 22 Aluminum electrolyzing cell with self-baking anode

Fig. 23 Carl Wilhem Söderberg (1876–1955) invented the self-baking anode for the aluminum electrolytic cell

emission of carcinogenic compounds during the self-baking process which was difficult to capture. In the prebaked system, the volatile organic matter is burned in the baking furnace and the heat generated improves the thermal efficiency of the process.

- In the prebaked cell, the anodes are mounted on a beam that can be adjusted vertically. Alumina feeders are placed in the center aisle between two rows of anodes. The cell is covered to permit collection of off-gases for processing in a gas-purifying system where volatile fluorides and other impurities are adsorbed on Al_2O_3 . In the Söderberg cell, the massive anode gradually descends at the rate of its consumption, and Al_2O_3 is added on the sides after breaking the crust.

Cell Arrangement

Since each cell takes a large current at low voltage, a number of cells (120–168) are arranged in series. The line voltage may be up to 800 V, and cell amperages 34,000–130,000 A. Figure 24 shows the electrical connections to one type of electrolytic cells.

Alumina Feeding

- In prebaked electrode cells, alumina feeding is more frequent and in smaller quantities through the center break-and-feed system which is composed of a volumetric alumina metering section and a mechanism for punching a hole in the crust. There are usually 3 to 5 point feeders fitted to each cell, each capable of delivering 1–3 kg of alumina. Because each feeder is actuated frequently, the holes often remain open, thus providing an escape vent for the anode gas. A general view showing the alumina supply is shown in Fig. 25.
- In Söderberg cells, feeding is done on the sides of the electrode.

Fig. 24 Electrical connections to one type of electrolytic cells

Discharge of Metal

When a sufficient amount of metal has accumulated in the bottom of the cell, it must be removed by tapping, ladling, or siphoning. This may be done every day, every second day or third day, depending upon the design of the cell. The molten aluminum is usually stored into a holding furnace so that the metal from many cells is blended. Practically, all commercial aluminum is remelted or heated in holding furnaces to ensure uniformity of compositions and the removal of nonmetallic impurities.

Energy Requirement

The voltage required for the deposition of aluminum is 4.64 V. About 38% of cell power (voltage) is lost due to the electrical resistance of the electrolyte. Reducing the anode-cathode distance is one way to decrease this loss. But this is limited by two factors:

- Increased reoxidation of reduced species.
- Increased possibility of short-circuiting due to magnetic turbulence (see below).

Fig. 25 General view showing the alumina supply hoppers in cells using prebaked anodes

In addition to the heating effect due to electrolyte resistance, a large amount of heat is generated due to the anodic reaction (oxidation of carbon). Loss of heat by radiation results in the formation of a frozen crust on the fused salt and a frozen ledge on the sides of the cell. The formation of the ledge is desirable because it protects the sidewalls of the cell against attack by the molten salt. The thickness of the ledge is a function of cell temperature: when the temperature increases, the thickness decreases and vice versa.

Cell Control

In a prebaked cell, there are usually 24 anodes, each is at a different stage of consumption and, therefore, has unique electrical properties. While oxidation of the anodes is offset by metal accumulation, individual anodes must still be adjusted so that each operates at the same amperage. Since new and partially consumed anodes have different electrical resistances and different surface areas, the anode-cathode distance must differ when the anodes are set to draw the same current. Precisely controlling such a system, so that each anode carries an equal share of the total current and is positioned slightly above the undulating metal pad while avoiding shorting, takes careful instrumentation and computer control.

Fluid Dynamics

- The large electric currents used in modern cells generate strong magnetic fields within the cell which exert forces producing movement of liquid conductors (molten aluminum pad) which may lead to electrical short-circuiting.
- Gas bubbles produce significant stirring in the electrolyte and are the dominant force in bath movement (Fig. 26).
- Natural convection due to temperature gradients or composition differences in the electrolyte are insignificant compared with the movement induced by magnetic forces and gas bubbles.

Today, cells over 250,000 A have been designed and operated with high efficiency by controlling magnetic turbulence to produce a more quiescent metal pad, thus permitting a reduction in the anode-cathode distance.

Anodes

Although there are two fundamental designs of anodes, they are both formulated from similar materials and undergo the same reactions within the cell. Petroleum coke of highest quality and a binding pitch (coal tar or

Fig. 26 Gas generation at the anode surface

petroleum pitch) are used for fabricating the anode. On pyrolysis, the pitch rigidly bonds the particulate coke. Anode quality affects both the energy efficiency and productivity of cells.

- About 10% of cell power is used to overcome the electrical resistance of the anodes.
- Dusting is caused by selective oxidation of the binder coke at the anode–bath interface, which releases aggregate particles into the electrolyte. Anode carbon that enters the electrolyte as dust is unavailable for electrolysis and adversely affects the current efficiency.

For environmental reasons, there has been an increasing tendency to move to the prebaked anodes. A comparison between the two anodes is given in Table 9.

Prebaked Anodes

These are formed by blending sized petroleum coke aggregate, crushed spent anodes, and coal tar pitch, molding this into blocks (with preformed electrical connection sockets) by pressing or vibration, and firing to $\approx 1100^\circ\text{C}$ in oil or gas-fired furnaces. Blending of sized fractions is important so that a compact solid can be obtained. A typical block is 70 cm wide $\times$ 125 cm long $\times$ 50 cm high. Electrical contact is made through aluminum or copper rods welded or bolted to steel stubs fixed in the anode socket by poured cast iron. The electrical resistivity of prebaked anode ranges from 0.005 to 0.006 Ωcm . Anode current density ranges from 6000 to 13,000 A/m^2 .

Table 9 Comparison between prebaked and self-baking anodes (Söderberg)

	Prebaked anodes	Söderberg
Electrical resistivity	Low	High
Density	High	Low
Pitch content, %	14–18	25–35
Anode consumption	Low	High
Power efficiency	High	Low
Anode effect	Rare	Frequent
Manufacturing cost	High	Low
Labor	High	Low
Al_2O_3 feeding	Central (easy)	Sidewise (difficult)
Collection of fumes	Easy	Difficult
Environmental problems	Low	High

Anode-baking furnaces are high-temperature heat exchangers applying indirect heating by combustion gases from fired fossil fuel (Fig. 27). The formed anode blocks are located in four to eight pits in each heat-exchanger section, with granular coke protecting against oxidation by flue gases and providing heat transfer from the flue walls. A furnace includes 28–48 sections in series located in two parallel rows with crossover connections at each end. Fans located at the outlet scrubber end provide a draft through a joint exhaust pipe surrounding the furnace. Ambient air is, thus, pulled through sections on cooling, to recover heat before entering the peak-fired and preheating sections. Exhaust manifolds connect each firing zone to the joint exhaust pipe.

Fig. 27 Anode-baking furnace: (1) concrete casting, (2) insulation, (3) section, (4) head wall, (5) flue channel, and (6) anode blocks and packing coke

On completion of the heat treatment, one section is disconnected at the cooling end while a new section is connected at the preheat end by moving the exhaust manifold to the next section in front. In this way, the firing zone is moved around the furnace. There are two main types of design:

- Two furnace concepts. The horizontal-flue (or open-top furnace), characterized by gas flowing through separate rows of flue-walls without coming into contact with the anode loads.
- The vertical-flue (or closed-top furnace). Gas flows are mixed in each section within the space between the lid and the pit top.

The pits are flanked on either side by combustion flues. Although the pits are separated by ceramic wall headers, the flues are interconnected. Before passing to the next flue, combustion products are forced to the bottom of the flue by ceramic baffles. An oil or gas air mixture is injected at the fuel input of the pit under fire and the combustion products pass through the next three pit flues before exiting by way of the waste gas manifold. Air for fuel combustion is preheated as it is drawn upstream of the fire through the three flues, containing previously baked anodes. The fuel injected represents about half of the heat necessary for baking; the other half comes from volatile matter in the

pitch which theoretically should provide more than enough heat to bake anodes.

Baked anodes are cooled by drawing air through the flues, producing preheated air for a regenerative burner system. The combustion products from the pit under fire operate in a recuperative manner by preheating the anodes. The waste gas manifold ties all of these rows of pits together by an underground flue at opposite sides of the pit assembly. When the anodes in a given pit reach the finishing temperature, the fire and manifold are moved to the next pit and the process is repeated. Maintaining uniform temperature distribution so that all anodes in a pit attain the desired temperature is an important requirement to avoid anode dusting.

While nearly all large aluminum producers have their own local facilities for manufacturing prebaked anodes, some depend on purchased anodes. The anode manufacturing complex in Rotterdam is the world's largest facility of this type, with an average capacity of 300,000 tons/year of prebaked anodes. The world's leading firm in the supply of anode paste plants for aluminum smelters is Buss AG, Pratteln, Switzerland.

Anode rodding (Fig. 28) serves to connect the anode blocks with the anode rods that feed electric current to the cells. The pins are first coated with graphite. The coating is then allowed to dry. The six stub holes in the anodes are heated to eliminate any moisture being present in the

Fig. 28 Rodding of anode blocks

Fig. 29 Fixing the rods in the anode blocks by pouring molten cast iron

holes prior to casting (Fig. 29). Finally, the anode blocks can be aluminum-sprayed before being ready for use. For proper functioning, the anode rod requires a reliable steel–aluminum transition joint, connecting the steel stub assembly with the aluminum anode rod. Consumed anodes are removed from the cell for replacement.

Söderberg Anodes

The Söderberg anode uses a premixed paste of petroleum coke and coal tar pitch which is added at the top of a rectangular steel casing that is typically 6–8 m long, 2 m wide, and 1 m high. Heat from the electrolyte and from the electric current bakes the carbonaceous mix as it passes through the casing to replace anode being consumed at the bottom surface. The baked portion extends past the casing and into the molten electrolyte.

The anode briquettes are made from petroleum coke and hard pitch. The coke is ground, blended, mixed with crushed pitch at 150°C, briquetted, then dumped into the top of the anode shell. The temperature at the top of the pot is high enough to melt the briquettes. The temperature in the lower part of the anode shell is high enough to distill the volatile matter in the briquettes and bake the anode into a single solid block. Electrical contact to the anode is achieved by steel pins (about 8 cm diameter), introduced through the pitch–carbon mixture, which is slowly converted to a carbonized mass when moving downwards to hotter zones as a consequence of the anode consumption. There are two designs depending on the method of making the electrical contact:

- *Horizontal Stud Electrodes.* These spikes are pulled and reset to a higher level as they approach the lower surface.
- *Vertical Stud Electrodes.* These are the more common electrodes as they are less labor-intensive and cause fewer operating disturbances. The pins are simply readjusted to compensate for the consumption of the carbon.

Although Söderberg anodes save the capital, labor, and energy required to manufacture prebaked anodes, their use is declining due to the following factors:

- Environmental problems associated with its operation.
- Higher electrical resistivity as compared to the prebaked electrode which causes lower power efficiency.
- Development of improved methods for fabricating the prebaked electrode, e.g., the vibrocompacting method.

Cathodes

The pool of aluminum in the bottom of the pot is the cathode. Contact is made by iron bars buried in the carbon lining. The carbon cathode must have adequate strength, good electrical conductivity, and be so fashioned that it will remain in place and carry the current to the metallic aluminum for 2–6 years. Overheating and local stresses cause it to crack and disintegrate. Broken pieces of lining may then float in the bath and cause partial short circuits between the anodes and the metal. Breaks in the lining may permit the molten aluminum metal to attack the steel shell.

In this case, it must be removed from the line for repair. The carbon lining is somewhat porous and absorbs nearly its own weight of the fused electrolyte. Borides and carbides of titanium and zirconium are being considered as future cathode material that could increase the life of the cell.

Anthracite and to some extent graphite and metallurgical coke are the major constituent in the cell cathode blocks. The anthracite is calcined at 1200°C, crushed and sized, mixed with coal tar pitch, molded into blocks and baked. These, along with carbonaceous seam mix, form the potlining. High purity is not as important as in the anodes since the dissolution of impurities is very slow. Consumption of cathode carbon amounts to 0.02–0.04 kg carbon/kg of aluminum produced. Two types of cathode linings are employed.

- Ramming a hot mixture of pulverized coke with tar and pitch binders into the steel shell, using a suitable cast-iron form to give the cavity the desired shape. The entire pot is baked in a furnace at about 600–800°C.
- Preformed and prebaked carbon blocks are used to build up the lining, the blocks being cemented together with a mixture of tar, pitch, and ground coke.

PURIFICATION AND REFINING

Molten aluminum tapped from the cell is transported to holding furnaces where recycled aluminum scrap is melted and alloyed. Oil and gas-fired reverberatory furnaces are commonly used to melt ingots for casting. To produce sound ingot, molten aluminum must be treated to remove nonmetallic inclusions, dissolved hydrogen, sodium, calcium, and other impurities. This purification is accomplished by a variety of systems where molten metal is filtered and/or fluxed during transfer between the holding furnace and the casting station.

In the rotating gas disperser method, argon–chlorine mixture is introduced through the shaft and exits beneath the disperser. The rotating action of the disperser forms tiny bubbles of gas that move upward through the molten

metal, creating an efficient cleansing action. Sodium and calcium levels are readily controlled in the 1–2 ppm range. Hydrogen reduction from 0.5 ml/100 g down to 0.1 ml/100 g are standard for most alloys at common metal flow rates. Some of the alloyed metal is shipped in molten form on special trucks to customers, e.g., in Germany.

Aluminum is the only metal refined electrolytically in a fused salt on an industrial scale. Aluminum produced by the Hall–Heroult process is normally 99.5–99.8% Al. The major impurities are silicon and iron. Higher-purity metal (99.99%) is mainly needed for electrolytic condensers. Two processes are used: electrolytic refining and the segregation process.

Electrolytic Refining

All electrolytic processes used (Table 10) are based on transferring aluminum from a lower anodic molten layer of impure aluminum, via an intermediate layer of molten salts, to a top cathodic layer of pure aluminum. The anode layer of impure aluminum is alloyed with 25–33% copper to make the density greater than that of the electrolyte at the working temperature of the bath which varies from 740°C to 1000°C. The electrolyte is a molten mixture of sodium fluoride and aluminum fluoride with other additions to give the desired density.

Because of the small difference in density between the three layers, the rapid increase or decrease in the density of the electrolyte with falling or rising temperature, the changes in anode alloy composition with time, and the possibility of circulation in the layers owing to the heavy currents in the associated magnetic fields, there was always the danger of mixing occurring, and in consequence, the contamination of the pure metal layer by the copper anode alloy. Operating the cell, therefore, requires great attention.

The cell is a mild-steel box lined with refractory brick (Fig. 30). The hearth consists of carbon blocks, cemented with carbon jointing paste, in which steel bars are embedded. The sidewalls are lined with magnesite bricks, backed by firebrick. Connection is made to the cathode layer by graphite blocks suspended from overhead. The graphite

blocks are usually jacketed to prevent oxidation by casting a 1 cm thick layer of pure aluminum around them. The anode layer is 25–35 cm deep, the electrolyte 15–25 cm thick, and the pure aluminum cathode layer 15–20 cm thick.

The aluminum to be refined is fed at intervals to the copper alloy through a wide graphite tube reaching down to the anode layer. Slow pouring ensures thorough mixing with the copper layer and avoids the floating of the impure aluminum upward through the electrolyte. The cell may be tapped daily by removing some metal in graphite ladles from the cathode layer. All operations must be carried out with a minimum of disturbance to the fluid layers.

Although little energy is theoretically required for the refining process, electrical power consumption is usually high – about 14,000–18,000 kWh/ton. The amperage of the three-layer cell is generally 30–60 kA, which is substantially lower than that of the Hall–Heroult process cell.

Segregation Process

Although the principle of purification utilizing the segregation phenomenon during solidification was well known, the process was first industrialized by Pechiney in 1975.

From 1981 to 1983, some Japanese companies independently industrialized the process, and the production capacity increased to about twice of that of the electrolytic process. The reason for this increase is that high-purity aluminum produced by the segregation process became usable for aluminum electrolytic condensers through improvements of electrolytic condensers in 1982. Refined purity is generally 99.98–99.99%, depending on the purity of the raw aluminum. The segregation process has several advantages compared with the electrolytic process, including lower plant and equipment cost, lower energy consumption and more flexible production rate. There are two types of segregation processes:

- The fractional crystallization process, in which purified aluminum crystals are formed to be separated from the liquid aluminum and are compacted to remelt and fractionally crystallize. In the Pechiney process, precipitated high-purity crystals are tamped in the bottom of the vessel to squeeze out molten impure metal between the crystals and fractional remelting and the growth of crystals occurs by appropriate heating.
- The unidirectional solidification or zone melting process, in which solidification progresses in the direction

inverse to the heat flow. In actual solidification, a high-impurity layer is formed in the liquid in the immediate vicinity of the liquid–solid interface. The impurity-concentrated layer is kept as thin as possible by mechanical stirring or by ultrasonic vibration of the liquid, and by heating the liquid while cooling the solid in order to get high purity and productivity. This process is suitable for mass production. To get higher purity, the refining process is repeated two or more times.

Ultrahigh-purity Aluminum

Ultrahigh-purity aluminum (meaning >99.999%) is produced by a combination of the electrolytic process and the segregation process or the zone melting process. In recent years, 99.9999% ultrahigh-purity aluminum has been produced. This material has uranium and thorium impurities of less than 1 ppb. The reduced content of radioactive elements is necessary to prevent errors associated with α -particle emission when aluminum is used as a conductor for ultralarge-scale integrated circuits.

ENVIRONMENTAL ASPECTS

The aluminum industry was one of the most polluting metal industries until recently when excellent measures were taken to render it a nonpolluting industry. Petroleum coke contains small amounts of sulfur; about 20% of this sulfur is emitted during the manufacture of the electrodes and the remaining during reduction. Organics identified

in the waste stream include benzo(α)anthracene, benzo-fluoranthene, benzo(α)pyrene, and phenanthrene; some of these are carcinogenic.

The amount of fluorine compounds emitted from a cell is at about 30 kg fluorine/ton aluminum produced. Reminding that the world production of aluminum is about 80 million tons, then fluorine emission from this source is about 2.4 million tons/year. Present technology eliminates or recovers about a half of this amount. Fluorine compounds originate from:

- Volatilization of bath components, e.g., AlF_3 .
- Reaction with air humidity and the formation of HF.
- Irregular operation during the anode effect.

The carbon oxides, diluted with ≈ 100 parts of air and containing fluoride values, are passed through dry or wet scrubbing systems where the fluorides are collected and returned to the cell. Carbon oxides are discharged to the atmosphere.

- *Dry Scrubbing.* The hydrogen fluoride is chemisorbed directly onto the crystalline alumina from the dry hot exhaust gas stream, which mixes and reacts with the alumina. The reacted alumina, as well as the particulate fluorides and any other particulates, are removed from the exhaust gas stream by bag filtration. The alumina collected is then fed to the cells (Fig. 31).
- *Wet Scrubbing.* Wet scrubbers are used to remove sulfur dioxide downstream of the dry scrubber. Wet scrubbers are also used to clean flue gases from the anode-baking furnace (Fig. 32).

Fig. 31 Absorption of fluorine compounds from gases leaving electrolytic cells by Al_2O_3 entering the cells

Fig. 32 Fume treatment system for controlling anode-baking furnace emissions

Spent Potlining

After a certain period of operation, the graphite which acts as cathodes deteriorates and has to be replaced. This is done by interrupting the operation, draining the electrolyte, allowing to cool, then replacing the blocks. The material removed is referred to as *spent potlining* and represents a large volume of solid waste. This material is hazardous because of its cyanide content that is mostly water-soluble (Table 11). The cyanide forms as a result of air leaks in the cell whose nitrogen content reacts with carbon at the high temperature of the operating cell. The reaction is known to be catalyzed by sodium salts in the same way as in the iron blast furnace.

Present disposal/management practices include temporary storage in curbed, roofed, protected areas to minimize leachate generation, and burial in landfills lined with impervious materials to prevent contamination of the surrounding environment. These procedures are costly, because of the large volumes involved. Because of its carbon and fluoride content, current research is directed

towards recovering or utilizing these valuable components. Potential routes for spent potlining include:

- Recovery and reuse of the fluoride and carbon constituents.
- Use as a flux material in the steel industry.
- Use as a supplemental fuel by cement manufacturers.
- Use as fuel in fluidized bed boilers.
- Destruction of cyanide in solution at high temperature and pressure.
- Crushing, grinding, mixing with CaSO_4 then injecting into a furnace to destroy the cyanides and bond the fluorides as CaF_2 .

DROSS TREATMENT

Dross is a major by-product of all processes involving molten aluminum. It is formed at the surface of the molten metal as it reacts with the furnace atmosphere. Up to 5% of the molten metal is turned into dross. This dross may contain as much as 75% of the free aluminum in the form of very small droplets entrapped in aluminum oxides and depending upon the metal being melted ingot or scrap, it can also contain lead, cadmium, or chromium. Processes have been developed to solve this problem.

The aluminum in the dross is usually recovered in oil or gas-fired rotary furnaces, various salts being added to increase the amount of aluminum recovered. This treatment produces a secondary dross containing alumina, salts, impurities, and a small amount of aluminum. Dross produced by melting pure aluminum is known as “white dross”, and the dross containing contaminants such as salt fluxes and other metals is known as “black dross”. Treatment in plasma furnace or electric arc furnace has also been suggested.

RECYCLE OF ALUMINUM

Aluminum scrap recovery has become an important low energy source of metal that requires only 5% as much energy to recycle as it requires to produce it from bauxite. A major recycling effort is aimed at beverage containers. New scrap, generated by plants making wrought and cast products, and old scrap recovered from obsolete products discarded by consumers, is returned to plants that cast ingot to produce mill products. Effective recycling of old scrap also lessens the consumption of bauxite, petroleum coke, and aluminum fluoride.

OTHER ROUTES FOR ALUMINUM

Although the Hall–Heroult process has gained industrial dominance, it has several disadvantages. The most serious are the high capital investment required and the high

Table 11 Typical analysis of spent pot lining

	Percentage
F	6–10
Na	12–19
Ca	1–2
CN ⁻	0–1

consumption of costly electrical power. There are also the costs of the alumina plant and of the carbon anode plant. Many of the aluminum-producing countries must import alumina or bauxite. The supply of petroleum coke is limited. These deficiencies have motivated researchers to find alternate processes.

Nonconsumable Anodes

Instead of reacting the oxygen generated at the anode with the anode material (carbon) to form CO and CO₂, it was conceived to use an inert anode to eliminate carbon as a raw material and recover oxygen as a by-product. The only known materials with any chance of success as nonconsumable anodes are metallic oxides, e.g., NiO and SnO₂. The advantages of inert anodes would be:

- Low labor intensity.
- Accurate and equidistant anode–cathode separation.
- Elimination of baking ovens.
- Production of a moderately valuable by-product, oxygen.
- Freedom from petroleum coke.

Tests, however, did not go beyond laboratory scale.

Composite Anodes

Anodes made of a mixture of 85% Al₂O₃ and 15% C, and baked at 900°C, were tested in a molten chloride–fluoride bath at 700°C as a possible substitute for the present technology. The advantages are: smaller anode–cathode distance and low energy consumption of about 9 kWh/kg Al, as compared to 12 kWh/kg in the present technology. However, the disadvantage is the larger weights and volumes of the anodes baked and handled.

Carbothermic Reduction

Crude aluminum or aluminum alloys may be produced by carbothermic reduction of Al₂O₃ or aluminous ores and SiO₂ at about 2000°C, followed by refining. Such process may have the following advantages: low capital and operating costs since reduction reactors usually have high productivity. Fluorides are not required. Bauxite can be reduced directly and local clays can be used. The carbon may be derived from coal. Total electrical energy is low if credit is taken for by-products. Carbon monoxide may be used to generate power.

To date, no such process has been commercially successful due to low yields, the high temperatures involved, and inefficient refining techniques. Only in Russia, aluminosilicate ores are smelted in electric arc furnaces to produce 60% Al–Si alloys.

Extrudable Al-Si-Mg Alloys: Simulation of Microsegregation and Homogenization

G.N. Haidemenopoulos and Panagiota Sarafoglou

Mechanical Engineering, University of Thessaly, Pedion Areos, Volos, Magnisia, 38334, Greece

Abstract

Extrudable Al-alloys of the 6xxx series are subjected to a homogenization treatment prior to extrusion in order to remove inhomogeneities generated during casting. Microsegregation of elements and phases is developed as a result of the solidification process. During homogenization, several phenomena take place such as the dissolution of various phases, the transformation of iron intermetallics, spheroidization of the remaining intermetallics, and reprecipitation during cooling. All these phenomena affect the extrudability of the material. An integrated simulation of microsegregation and homogenization is described. Microsegregation is simulated with the application of the Scheil-Gulliver model, employing computational thermodynamics. A Dual Grain Model has been developed for the simulation of homogenization, taking into account the variability of the grain size in the as-cast material. In this way, it is possible to simulate the dissolution of Mg_2Si and the transformation of iron intermetallics concurrently. The results of the simulations provide a deeper understanding of the effects of processing on alloy microstructure and can be used toward the design of the homogenization process of extrudable Al-alloys.

Keywords: Extrudable aluminum alloys; Homogenization; Microsegregation.

INTRODUCTION

Extrudable aluminum alloys of the 6xxx series (Al-Mg-Si) find significant applications to the building, construction, and transportation sectors due to the excellent strength/ductility properties combined with reduced weight and oxidation resistance. Large-scale ingots or billets, suitable for extrusion, are produced with the direct-chill casting method. The as-cast material exhibits low formability due to microstructural inhomogeneities, arising from the solidification process and alloy chemistry. Major inhomogeneities in the as-cast material include elemental microsegregation in the level of the secondary dendrite arms, grain boundary segregation, and the formation of several low-melting eutectics and intermetallic compounds, which degrade the extrudability of the as-cast billet. These effects can be partially or completely eliminated with the application of a homogenization treatment of the as-cast billets. The benefits of this treatment include the following: removal of elemental microsegregation, dissolution of low-melting eutectics, transformation of iron-containing intermetallic compounds, shape control (round-off) of hard particles with sharp edges, dissolution of the grain-boundary Mg_2Si phase, and re-precipitation with a more homogeneous ingrain distribution during

homogenization cooling. All these effects improve the extrudability and increase the response of the material to natural or artificial aging.

The aim of the present article is (a) to review current literature on the issues of microsegregation and homogenization and (b) to show how the application of computational alloy thermodynamics and kinetics can be used for the simulation of microsegregation and homogenization in an effort to quantify the effect of processing parameters and alloy chemistry. The article is organized as follows: In “Literature Review” section, a literature review is presented on the microsegregation resulting from the casting of aluminum alloy billets as well as on the homogenization treatments applied to remove microsegregation. “Simulation of Microsegregation” section deals with the simulation of microsegregation and the development of the as-cast microstructure. “Simulation of Homogenization” section deals with the simulation of the homogenization treatment and the phase transformations, which take place during homogenization. Finally, in “Implications to Alloy and Process Design” section a discussion on the implications of the simulation results in alloy and process design is presented with the aim to develop high-strength and high-extrudability aluminum alloys.

LITERATURE REVIEW

Extrudable aluminum alloys of the 6xxx series, based on the Al-Mg-Si system, are subjected to a rather complicated process chain involving melt treatment, casting, homogenization, preheating, extrusion, and aging. Large-scale ingots or billets, suitable for extrusion, are produced with the direct-chill casting method. The solidification path of these alloys is quite complex and consists of binary, ternary, and even more quaternary eutectic reactions.^[1,2] A list of the invariant reactions observed during the solidification of these alloys is given in Table 1.^[3–6]

The as-cast material exhibits low formability due to microstructural inhomogeneities, arising from the solidification process and alloy chemistry. Major inhomogeneities in the as-cast material, which degrade the extrudability of the as cast billet, include the following:

- Elemental microsegregation in the level of the secondary dendrite arms.
- Grain boundary segregation and formation of several low-melting eutectics.
- Formation of intermetallic compounds.

Among the intermetallics, the most important are the Fe-bearing intermetallics, $\alpha\text{-Al}_{12}(\text{FeMn})_3\text{Si}$ and $\beta\text{-Al}_5\text{FeSi}$, from now on called $\alpha\text{-AlFeSi}$ and $\beta\text{-AlFeSi}$, respectively. The $\alpha\text{-AlFeSi}$ has a cubic crystal structure and globular morphology while the $\beta\text{-AlFeSi}$ possesses a monoclinic structure and a plate-like morphology, limiting the extrudability of the as-cast billet by inducing local cracking and surface defects in the extruded material.^[1,7] The disadvantage of high Fe content in these alloys is the enhanced probability of forming large particles of $\beta\text{-AlFeSi}$, with a detrimental impact on the extrudability of the alloy.^[8] Despite their importance, there has been a rather limited attention to the control of Fe-intermetallics in the as-cast microstructure, most important being the effect of cooling rate^[9–11] and the spatial dispersion of intermetallics in the microstructure.^[1,12,13]

The detrimental effects of microsegregation can be partly or completely eliminated by the homogenization heat treatment of the cast billets. The main benefits of this process are the following:^[14]

- Removal of microsegregation.
- Removal of nonequilibrium low-melting point eutectics, particles, and segregation gradients that will give areas with low-melting point in order to avoid cracking or tearing during subsequent hot working.
- Shape control (round-off) of hard particles with sharp edges, such as Fe-based intermetallics, which results in poor ductility.
- Formation of secondary particles (dispersoids) for grain size control during extrusion or rolling.
- Uniform distribution of alloying elements in solid solution before extrusion or rolling and age hardening.

Industrial homogenization for aluminum alloys is a three-step process involving heating, holding to high temperature and cooling. Major reactions during holding involve the dissolution of Mg_2Si , the transformation $\beta\text{-AlFeSi} \rightarrow \alpha\text{-AlFeSi}$, which is important due to the moderate high-temperature ductility of the β -phase,^[4,15] coarsening of dispersoids, and the spheroidization of undissolved $\alpha\text{-AlFeSi}$ particles. A high temperature below the liquidus temperature is usually selected for homogenization in order to reduce the process time. Soft 6060 and 6063 alloys are best homogenized at higher temperatures than harder alloys such as 6061 and 6082.^[16] Local melting can cause severe damage at the alloy microstructure inducing voids, cracks, and blistering during extrusion.^[7] Segregated regions can be melted at lower temperatures from the solidus temperature. Consequently, a safe limit for the homogenization temperature should be the eutectic temperature for the Mg_2Si invariant reaction.

The microstructure evolution of the 6063 alloy during homogenization has been studied in the work of Biroli^[17] for various thermal cycles. In particular, the Mg_2Si dissolution during homogenization has been studied with electrical resistivity, while the distribution of the alloying elements has been studied with electron microprobe analysis for the 6061, 6069 alloys.^[18] The dissolution and coarsening kinetics of the Mg_2Si particles during reheating of the homogenized material has been discussed in the work of Usta, Glicksman, and Wright and Van der Langkruis.^[19,20]

The transformation of $\beta\text{-AlFeSi} \rightarrow \alpha\text{-AlFeSi}$ has been modeled for short homogenization times in the work of Kuijpers,^[21] and the effect of Mn and Si on the kinetics of the transformation is discussed in.^[22] After the completion of the $\beta\text{-AlFeSi} \rightarrow \alpha\text{-AlFeSi}$ transformation, the undissolved $\alpha\text{-AlFeSi}$ phase undergoes morphological changes, which involve rounding of edges, pinching, and necklace formation. Such changes have been described in Refs. [9,23,24] and a quantitative characterization of the

progress of the homogenization, based on microstructural indices, such as the aspect ratio and circularity, was recently presented in the work of Sarafoglou.^[25]

During the cooling step, reprecipitation of Mg_2Si takes place. The distribution and size of the Mg_2Si particles formed during cooling are important parameters influencing extrudability. Several authors studied the influence of the cooling rate after homogenization on the alloy microstructure. The influence of the cooling rate on the final mechanical properties for the 6063, 6082, and 6005 alloys has been studied in Refs. [26,27], while the influence of the cooling rate on the extrusion speed for various chemical compositions of AlMgSi alloys is discussed in the work of Reiso.^[28] Precipitation during homogenization cooling, including the effect of cooling rate, has also been discussed in Refs. [29–31]. It appears that the precipitation of the metastable β' - Mg_2Si phase instead of the equilibrium β - Mg_2Si phase enhances the extrudability of the material.^[26]

SIMULATION OF MICROSEGREGATION

Microsegregation during the complex solidification process of Al-Mg-Si alloys is simulated by employing the Scheil-Gulliver model^[32,33] with the main assumption that the diffusion coefficient of the components in the liquid phase are infinitively fast whereas in the solid are zero. The assumption of negligible diffusion in the solid is acceptable due to the short local solidification time encountered in industrial direct-chill casting conditions. Along each step in the cooling process during solidification, local equilibrium is established at the solid/liquid interface and the compositions of the solid and liquid phases are given by the phase diagram. Also along each step, the solid phase formed retains its composition, and the liquid composition is always homogeneous. The composition of the solid C_s at a fraction of solid f_s is given by the Scheil equation, which for a binary system is

$$C_s = C_0 k (1 - f_s)^{k-1}$$

where C_0 is the alloy nominal composition and k the partition coefficient. For multicomponent alloy systems, the Scheil-Gulliver model has been implemented in the so-called Scheil module of the Thermo-Calc Software.^[34]

A typical solidification path, for the 6060 alloy with composition Al-0.38Mg-0.40Si-0.2Fe-0.03Mn (mass%) is shown in Fig. 1a as temperature vs. mass fraction solid. The phase sequence during solidification is fcc $\rightarrow$ α -AlFeSi $\rightarrow$ β -AlFeSi $\rightarrow$ Mg_2Si $\rightarrow$ Si (diamond). The arrows depict the temperature and the mass fraction of solid where each phase starts to form. The liquidus temperature for this alloy was calculated to be 656°C and the solidus temperature is 557°C.

The mole fraction of phases formed during solidification is shown as a function of temperature in Fig. 1b. Formation of α -AlFeSi starts at 630°C while further formation of α -AlFeSi stops, when the β -AlFeSi starts to form at 610°C. The Mg_2Si phase starts to form at 575°C and continues to grow simultaneously with the β -AlFeSi phase until the quaternary eutectic temperature (557°C) is reached and the remaining liquid transforms to a mixture of fcc, β -AlFeSi, Mg_2Si , and Si.

The phases mentioned earlier are not distributed uniformly in the microstructure but segregate to regions where the liquid solidifies last, i.e., close to grain boundaries. This phase segregation is depicted in Fig. 2a, which gives the mole fraction of all phases vs. fraction solid (fcc matrix is excluded). It is seen that the α -AlFeSi phase forms above 85% solidification, while all other phases form above 95% solidification. This means that the intermetallic phases form at the secondary dendrite boundaries toward the end of solidification. Accordingly, the microsegregation of the alloying elements in the fcc matrix follows a similar trend, i.e., increases toward the end of solidification, as shown in Fig. 2b. The drop in the concentration profile of Mg and Fe is attributed to the formation of Mg_2Si and iron intermetallics, respectively.

The as-cast microstructure is shown in Fig. 3. The dendritic structure and the resulting interdendritic microsegregation are depicted in Fig. 3a, while the network of intermetallic phases is depicted in Fig. 3b.

As stated in the introduction, regarding the as-cast structure, the most important phase limiting the extrudability is the β -AlFeSi iron intermetallic. Therefore, the fraction of this phase should be minimized also in the as-cast structure in order to make homogenization more efficient. At the same time, the effect of Mn as an alloying element influencing the fraction of the β -AlFeSi is investigated. A map of the β -AlFeSi phase fraction in the Mg-Si composition space is depicted in Fig. 4 for two Mn levels, 0.03 and 0.45 mass% in alloys containing 0.2 mass% Fe.^[35] The mole fraction of the β -AlFeSi phase decreases toward the lower right corner of the contour plot, indicating that low β -AlFeSi can be obtained at lower Si and higher Mg contents. The 0.45% Mn iso- β lines lie above the respective 0.03% Mn iso- β lines, indicating that for fixed Mg content, higher Mn allows the use of higher Si, without further increase of β -AlFeSi since Si stabilizes β -AlFeSi. The spacing between the iso- β lines for the two Mn levels increases toward the upper left corner of the contour plot, indicating that the effect of Mn, in reducing β -AlFeSi, becomes stronger at higher Si and lower Mg contents.

SIMULATION OF HOMOGENIZATION

As mentioned earlier, the detrimental effects of microsegregation can be partly or completely eliminated by the homogenization heat treatment of the cast billets. The

Fig. 1 (a) Solidification path of the 6060 Al-alloy, (b) Mole fraction of phases formed as a function of temperature during solidification

aim of the simulation of the homogenization process is to determine the temporal and spatial evolution of the Mg_2Si dissolution and the β -AlFeSi $\rightarrow$ α -AlFeSi transformation. The solution of this problem involves multicomponent diffusion in a multiphase system. The problem can be treated only numerically, and relevant work has been presented in the past for the dissolution of Mg_2Si in 6061^[36] as well as the β -AlFeSi $\rightarrow$ α -AlFeSi transformation.^[37] The basic principles will be given here based on the work in the work of Sarafoglou.^[25] Due to the variability in grain size, a Dual Grain Model (DGM) is considered. The calculation domain consists of two grains attached to each other as depicted in Fig. 5. Following metallographic

examination, two sizes of 90 and 20 μm radius, respectively, were selected for the construction of the DGM. The calculation domain is then the representative volume element (RVE) for the solution of the homogenization problem. The boundary conditions of the problem are zero flux of all elements at $x=0$ and $x=L$ (closed system). The initial conditions of the DGM are the profiles of the elements and phases resulting from the Scheil-Gulliver simulations, which were presented in the previous section. So the profiles in Fig. 2a and 2b were used as the initial conditions of the homogenization problem. In this way, there is a direct link between the microsegregation model and the homogenization model. The problem is solved with the DICTRA

Fig. 2 (a) Microsegregation of phases and (b) Microsegregation of elements in a 6060 Al-alloy

software,^[38] which takes into account temperature and composition-dependent diffusivities. The Mg_2Si , α -AlFeSi, and β -AlFeSi phases were entered as dispersed phases in the matrix fcc Al solid solution phase. The dispersed phases were treated as “non-diffusion phases”, meaning that diffusion takes place only in the matrix and the dispersed phases act as sources or sinks of alloying elements, when dissolution or precipitation take place, respectively.

The evolution of the volume fraction of intermetallic phases during homogenization at 580°C is depicted for the 6060 alloy in Fig. 6. It is evident that the dissolution of Mg_2Si is very fast while the β -AlFeSi $\rightarrow$ α -AlFeSi

transformation is completed at 220 s. The spatial evolution of the Mg_2Si dissolution is depicted in Fig. 7 for three times 0, 5 and 10 s. The transformation is much faster in the smaller grain, since at 5 s the Mg_2Si has already dissolved in the smaller grain, while there is some Mg_2Si still remaining in the larger grain. The spatial evolution of the β -AlFeSi $\rightarrow$ α -AlFeSi transformation is depicted in Fig. 8a–c for 50, 100, and 500 s at 580°C. Two interesting features to be considered are (a) the transformation starts at a distance away from the boundary while the transformation front moves toward the boundary and (b) there is an exact correspondence between the profiles of the α -AlFeSi

Fig. 3 As-cast microstructure of the 6060 alloy: (a) Dendritic structure and (b) Network of intermetallic phases

and β -AlFeSi phases, i.e., where there is a reduction in β -AlFeSi, there is a corresponding increase in α -AlFeSi.

An X-ray diffraction spectrum for alloy 6060 homogenized at 560°C for 30 min is depicted in Fig. 9. The presence of peaks corresponding to the α -AlFeSi phase and the absence of peaks corresponding to the β -AlFeSi phase indicate the completion of the β -AlFeSi $\rightarrow$ α -AlFeSi transformation. The microstructure of the homogenized material is shown in Fig. 10 for homogenization of the 6060 alloy at 580°C for 2 h. Fig. 10a is an optical micrograph indicating that in several locations the α -AlFeSi phase is arranged in a necklace formation, i.e., a formation of isolated spherical particles along the grain boundaries. The necklace formation is more evident in the SEM image of Fig. 10b. Necklace formation indicates that the homogenization is at an advanced stage.

IMPLICATIONS TO ALLOY AND PROCESS DESIGN

New demanding light-weight applications in the automotive and aircraft sectors require the development of high-strength alloy extrusions. Such applications include pillar and chassis structural parts in vehicles and wing or fuselage reinforcement parts in aircrafts. The increase of strength is possible with higher alloying with Mg and Si, in order to form higher amounts of the strengthening phase Mg_2Si (e.g., 6061 and 6082 alloys). However, increased alloying deteriorates the extrudability, leading to extremely low extrusion speeds for the high-strength alloy systems. In the other end of the spectrum, i.e., low-alloy low-strength applications (e.g., 6060 or 6063 alloys), the main industrial requirement is to increase the

Fig. 4 Contour plot of fixed mole fraction of β -AlFeSi in the as-cast microstructure of Al-Mg-0.2Fe-Mn alloys (full lines 0.03 Mn, dotted lines 0.45 Mn, mass%)

Fig. 5 The solution domain of the dual grain model (details in text)

extrusion speed, in order to increase production rates. In both cases, it appears that extrudability is the key property that should be controlled and improved through a carefully designed homogenization process. So far, the problem has been tackled in a rather erratic way, involving heavy trial-and-error laboratory or even industrial experiments to figure out the effect of alloy chemistry and homogenization process parameters such as the homogenization temperature and time and the cooling rate following homogenization. In most cases, only individual aspects of the process are considered and the effect of prior processing is often neglected.

As long as alloy composition is of concern, mapping over the composition space of relevant microstructural quantities is very useful. Such maps have been developed, for example, for the as-cast microstructure^[35] and an

example is shown in Fig. 11. The mole fractions of both the Mg_2Si and the β -AlFeSi phases are mapped over the Mg-Si composition space. The Mg_2Si phase is the strengthening phase and the β -AlFeSi the undesirable iron intermetallic. The mole fractions of the β -AlFeSi phase range from 0.001 to 0.005 while those for the Mg_2Si range from 0.002 to 0.009. The position of alloys 6060 and 6063 is also indicated on the maps. Both alloys possess a low fraction of β -AlFeSi indicating an excellent extrudability potential. The Mg_2Si is maximized toward the upper right corner while the β -AlFeSi phase is minimized toward the lower right corner of the maps. This allows selection of optimum compositions for favorable as-cast microstructures in terms of the two phases.

Regarding extrudability, it appears that the homogenization treatment plays the most important role in

Fig. 6 Evolution of the volume fraction of intermetallic phases vs. time during homogenization of the 6060 Al-alloy

Fig. 7 Spatial evolution of the mole fraction of Mg_2Si at the early stages of homogenization of the 6060 alloy at $580^\circ C$

establishing the appropriate microstructure. For example, an optimum homogenization treatment has been determined for a 6060 alloy in the work of Birol,^[39] which ensures a homogeneous structure with round α -AlFeSi particles and sufficiently low hardness. In addition, it has been shown in the work of Zajac, Bengtsson, and Jonsson^[26] that the rate of homogenization cooling also influences the extrudability, since it affects the precipitation of Mg_2Si during cooling. The DGM model presented in “Simulation of Homogenization” section can be used

to estimate minimum homogenization times, for the dissolution of Mg_2Si and the β -AlFeSi $\rightarrow$ α -AlFeSi transformation. However, the actual homogenization times are longer in order to achieve the spheroidization of the intermetallic phases. Modeling and simulation efforts are underway for both processes, i.e., spheroidization of intermetallics during homogenization and Mg_2Si precipitation during homogenization cooling toward a simulation-based design of the homogenization process of extrudable Al-alloys.

6 CONCLUSION

An integrated simulation of microsegregation and homogenization of extrudable Al-alloys has been presented. Microsegregation of elements and phases has been simulated with the application of the Scheil-Gulliver model, employing computational thermodynamics. A Dual Grain Model has been developed for the simulation of homogenization, taking into account the variability of the grain size in the as-cast material. The multicomponent diffusion problem has been solved, and it was possible to simulate the dissolution of Mg_2Si and the transformation of iron intermetallics concurrently, providing estimations for the minimum homogenization time. The results of the simulations provide a deeper understanding of the effects of processing on microstructure and can be used toward the design of the homogenization process of extrudable Al-alloys.

ACKNOWLEDGMENTS

The authors are grateful to Prof. E. Pavlatou of NTUA for her assistance with the XRD analysis. The supply of material for this research by the Aluminium of Greece (AoG) is also appreciated.

Extrusion

Sigurd Stvren and Per Thomas Moe

Norwegian University of Science and Technology, Trondheim, Norway

Abstract

The article will provide the reader with practical aspects of extrusion as well as an overview of the theoretical work and current challenges of this important aluminum alloy processing technology. This article is divided into three main sections: basic parameters for designing a section or die, an overview of extrusion processing, and optimization of productivity, cost and quality. Specific topical coverage includes: basic extrusion parameters, manufacturing of extrusions process review, productivity, quality including dimensional stability, surface quality, corrosion, cracking and tearing, product development and design, overview of the metallurgy of the extrusion process, numerical analyses and more.

Keywords: Design; Dimensional stability; Mechanical properties; Surface quality.

INTRODUCTION

This chapter is devoted to extrusion of aluminum alloys and divided into three main sections. “Basic Parameters of Extrusion” section covers the basic parameters of extrusion needed for designing an aluminum section and a die, for understanding the processing steps, and for optimizing productivity, cost and product quality. A specific section shape is used to illustrate the interaction between these parameters. “Applications, Alloy Selection and Design Considerations” section is focused on the commercial applications aspects of extruded sections, life cycle aspects, alloy selection and section design guidelines. “The Extrusion Process” section covers the extrusion process in some detail, focusing on the basics of quantitative modeling of metal flow in the container and through the die. In the final section, some of the outstanding research challenges in the theory of extrusion of thin walled aluminum sections are discussed: (1) 3D-modeling of thin-walled extrusion; (2) the bearing channel friction in interaction with die deflections and section surface formation; (3) stability of flow; and (4) limits of extrudability.

The intention is that the chapter should give the reader an overview of the practical aspects of extrusion as well as an understanding of the present state of the theoretical work and some challenges in this branch of metal forming science and technology. However, the study of extrusion as a process is both relatively complex and multidisciplinary, and this chapter can hardly give the answer to all problems that may be encountered. Thus, before making detailed section design and alloy decisions, the reader is advised to contact an extrusion plant. Even though theoretical and experimental work has managed

to explain a number of relevant phenomena, the quality of an extruded profile and naturally also of a complete product based on extrusions is still mainly dependent on the experience of personnel close to or at the extrusion plant. One may also confer with more general works on extrusion.^[1,2]

BASIC PARAMETERS OF EXTRUSION

The Process

The most common method for producing aluminum profiles is that of direct extrusion (Fig. 1). Here, the ram is moving into the container at one end, and pushes the billet through the opening of the die at the other end. The temperature of the deforming aluminum alloy is in the range of 450–600°C during the process cycle. In contrast to the extrusion of steel, aluminum extrusion is taking place in absence of any lubrication of the die. Hence, the material sticks to the container and the die, giving a highly inhomogeneous flow with large degree of visco-plastic shear flow (See “The Extrusion Process” section). The material far a way from the wall is flowing easier than that closer to it, with the surface of the billet remaining in the container. The billet and the container are normally circular cylindrical, but can in special cases be rectangular with rounded corners.

A special feature in extrusion of aluminum alloys is the production of hollow sections (Fig. 2). In this case the metal flows into the opening between the die and the mandrel. The mandrel is kept in position by bridges. The billet material is forced, by the movement of the ram, into the portholes in the bridge die, called the feeder ports.

Fig. 1 Direct extrusion of an open section

Fig. 2 Direct extrusion of a hollow section

Under the bridges, adjoining metal streams meet and are forgewelded together in the weld chamber, before flowing through the bearing channel, i.e. the opening between the die and the mandrel.

Besides direct extrusion, two other special extrusion methods are used, indirect extrusion, and continuous extrusion, the Conform method.^[3] In indirect extrusion (Fig. 3) the die is pushed into the container, where as the extrudate is flowing in opposite direction through the hollow stem. In the continuous extrusion (Fig. 4) a continuous feedstock is fed into a groove in a rotating wheel. Pressure is built up by friction between the groove walls and the feedstock in the gap between the wheel groove, the feeder plate and the abutment. The metal is then forced to the die opening in a continuous flow. Both open and hollow sections can be produced.

Extrusion in rectangular containers, indirect extrusion and continuous extrusion are used for special products in limited quantities. Therefore, in the rest of this chapter the direct extrusion of open and hollow sections are dealt with.

The main parameters of the billet, the container and the extruded section are (Fig. 1):

- Diameter of the container: $D_c [\text{m}]$
- Cross section area of the container: $A_{\text{container}} = A_c = \frac{\pi}{4} D_c^2 [\text{m}^2]$
- Billet weight: $W_b = \rho \frac{\pi}{4} D_b^2 L_b [\text{kg}]$

- Billet diameter: D_b [m]
- Billet length: L_b [m]
- Density of aluminum: $\rho = 2700$ [kg/m³]
- The circumscribed diameter of the section: d [m]
- Section thickness: t [m]
- Cross sectional area of the section: $A_{\text{section}} = A_s$ [m²]
- Weight of section per meter length: $w_s = A_s \rho$ [kg/m]
- Reduction ratio: $R = \frac{A_c}{A_s}$

The most common values for the diameter of the container are 0.178 m and 0.208 m. The billet diameter is usually 5–10 mm less than the container diameter, allowing the billet to enter the container easily. The circumscribed diameter of the profile is usually less than 0.9 times the diameter of the container, but specially designed dies with

a so-called expansion chamber may actually allow for $d > D_c$. The section thickness often varies over the cross section of the profile. The reduction ratio is normally in the range of 20–80. If R is very high ($R > 70$) and the section is of a proper shape, the die is usually designed with more than one die opening (Fig. 5). In this case, the reduction ratio is:

$$R = \frac{A_c}{A_s n} \quad (n = \text{number of die openings})$$

When an extrusion press cycle is carried out (see “The Extrusion Process” section for details), a small part of the billet is left in the container, the discard (Fig. 6). The length of the discard is normally around 10–20 mm.

- Discard length: L_d
- Discard weight: $W_d = \rho \frac{\pi}{4} D_c^2 L_d$ [kg]
- The weight of the extruded section: $W_s = W_b - W_d$ [kg]
- Length of the extruded section: $L_s = \frac{W_s}{w_s}$ [m]

Fig. 3 Indirect extrusion

Fig. 4 Continuous extrusion

Fig. 5 A multihole die

Fig. 6 Billet, discard, and the extruded section

The Die

The tooling package is to perform the deformation of the aluminum and must naturally withstand very large forces. Tools are generally made of high strength steels such as H11 and H13, and surface in direct contact with the flowing material is hardened through nitriding prior to any use. Furthermore, the complete tooling package will be comprised of a great number of parts which all are meant to support the die when pressure is applied by the stem. The complete tooling package will be designed differently for the extrusion of hollow or open profiles. In any case, however, a bolster will be situated directly behind the die and provide the main support. The die and bolster will then be placed in a horseshoe clamp, which is firmly attached to the press structure.

In the case of extrusion of open sections one die design does not differ significantly from another although the bolster may provide varying degrees of support. Various die designs have, however, been developed for the extrusion of hollow profiles. The names of the most commonly used die types are porthole, spider and bridge, and for the extrusion of 6XXX-alloys porthole dies have traditionally been most popular, partly due to the ease with which they can be cleaned after extrusion.

The design of a porthole die is displayed in Fig. 7. The outer contour of the section is formed by the die plate (Fig. 7a). The tongue will be less stiff and weaker than the rest of the plate because it supports the pressure from the deforming material on the tongue only along one edge. The inner circumference of the section is formed by the mandrel Fig. 7b. The mandrel is an integrated part of

the porthole die, connected to the rest of the die by webs, or bridges. In the mandrel a groove is machined out. This groove enables the internal rib in the hollow section to be formed.

The deforming alloy is flowing over the bridges and down into the feeder ports. Under each bridge, in the weld chamber, the two neighboring metal streams are forge-welded together. In this process the temperature of the material will not exceed that of melting, but welding will take place due to high pressures and diffusion rates. The alloy is also flowing into the groove in the mandrel from two sides, and in the center of the groove the two streams of metal are forge-welded, before the material flows into the bearing channel. All such welds are denoted seam welds. If pressures are not high enough in the weld zones, insufficient welding will take place. Furthermore, if material flows in an uncontrolled manner, one will not be able to predict the exact position of the weld. All these phenomena are highly unwanted and, hence, detailed studies of such can be found in the literature.^[4]

When designing mandrels one has to keep the following in mind:

- The stiffness and strength of the bridges should be optimized. The feeder ports should at the same time be as large as possible in order to reduce the load on the mandrel and allow for higher extrusion speed. This will, however, result in a weak bridge construction

with unwanted flexibility and an increased risk of die deflection.

- Controlled flow out of the bearing channel should be sought. The die and the bearing channel should be designed so that the section leaves the bearings at a uniform speed and without generating excessive tensile or compressive stresses. Of special importance is the control of metal flow and die welding of the inner rib, because this cannot be inspected from outside during the press cycle.
- The surface of the section should be homogeneous and leave the die without streaks and stripes at the highest acceptable speed.

Clearly, there is a complex, but a very fascinating design-optimizing challenge here. Today, die design competence exists mainly as practical knowledge by highly skilled die designers, die producers and die correctors in the die shops. As will be pointed out in Secs. 4 and 5, however, the development of 3D computer simulation of hot extrusion processes is approaching such a level of precision that it can be used as a tool for die design. It must, however, be done in close cooperation with skilled and experienced die specialists.

The Manufacturing System

Satisfactory control of the material flow may be viewed as the key element in a successful production

Fig. 7 Billet, die, and extruded section in the process of extrusion

of aluminum profiles. In this context the last assertion has two alternative interpretations, and both are in fact equally correct. In order to produce extrusions with the desired quality at an optimum pace, one has to establish some sort of an understanding of the mechanisms of plastic flow of material in the container and die. However, if an enterprise is to succeed economically in the extrusion business, it is as important that it masters the logistics, that is the control of the material flow in and around the production facilities. The extrusion process is carried out in an extrusion plant, which often has a lay out similar to that presented in Fig. 8. Although heat treatment in general is the most time consuming part of the production system, other process steps may in fact constitute the actual bottlenecks. The pressing of profiles is one such as it is non-continuous, and as considerable time is spent on changing dies, reloading new material into the container and performing maintenance tasks. Procedures are made even more complicated as new production orders for profiles often may necessitate several trial runs on the press. If the material is not transported effectively, down times may easily be long, and the most important parameter of all, productivity, will, consequently, be low.

As is seen on Fig. 8 the extrusion process is comprised of a great number of steps. One of the most important, however, is the production of raw material for the process, and this usually does not take place in the plant. Feed stock for the process is logs, normally in lengths of 6–7 m. They are supplied from the cast house of primary aluminum smelter or a secondary (recycled) aluminum cast house. The logs are produced as visualized in Fig. 9.

The liquid metal at temperature above 700° C is cleaned, added alloying elements and grain refiner before entering the casting table. By passing the casting molds with direct water cooling, the liquid aluminum alloy solidifies into a log. After casting, the log is homogenized in a temperature cycle that secures the best possible extrudability by establishing a homogeneous distribution of alloying elements and by dissolving phases with low melting points, typically Mg_2Si .^[5,6] The logs are then transported to the extrusion plant.

In the plant a number of distinct processing steps takes place (Fig. 8). The logs are first taken one by one from the log stacker and transported to the induction heater. Here, a certain temperature profile is imposed on the log, and it is then cut into billets of a prescribed weight. In some plants the logs are cut prior to any heating.

The billet is then loaded into the extrusion press, where the ram pushes it into the container. The end of the billet surface in contact with the ram, has been given a coating so that it does not stick to the *dummy block* between the ram and the billet. Because the billet has smaller diameter than the container bore, it is given an upsetting in order to fill the container. In this phase there is a risk of entrapping air in the container, and, thus, the ram stops after upsetting, unloads, and moves a small distance backwards to let the possible entrapment leave. This is called the *burp cycle*.

Thereafter, the extrusion process commences. The ram pushes the billet through the die opening. The load capacity of the press with a container diameter of 0.178 m is normally 16 MN, which corresponds to a specific pressure of 643 MPa. If the container diameter is 0.208 m, the load capacity is normally 22 MN and the specific

Fig. 8 Layout of an extrusion plant

Fig. 9 Direct chilling casting (DC-casting) of logs

pressure 647 MPa. The temperature of the billet prior to extrusion is in the range 450–470°C. In the induction heater, the billet may have been given varying temperature along its length in order to compensate for the heat generation caused by the shearing along the container walls when it is pushed through the container (see also “The Extrusion Process” section). This is called *tapering*, and the highest temperature is usually in the front end of the billet. The temperature of the section leaving the die is in the range of 550–600°C. The taper should be given in such a way that the run out temperature is constant as this will result in minimum variation of dimensions and properties during the press cycle.

As the section front leaves the die, it is gripped by a *puller*, which guides the section out on the *run out table*. The profile is then quenched and further cooled down when moving sideways along the table. The lengths of the profiles upon leaving the die may be from 20 to 50 m, depending on the length of the billet and the reduction ratio. Normally, a number of charges (billets) are performed with the same die in a production set up. In this case, one may weld the profile from the new charge directly to the one produced in the foregoing charge, creating a so-called *charge weld*. This procedure simplifies production, but necessitates cutting of the profile during extrusion. On the cooling table the section is given a plastic deformation of 0.5–2% elongation in order to eliminate internal stresses due to uneven cooling over the cross section of the profile and straighten up possible bends and twists before going into the cutting saw. The extruded section is finally cut into prescribed lengths, normally 6 m.

The process of cutting may vary somewhat from one plant to another.

The cut sections are stacked in bins and transported through the aging oven where they spend 3–6 hr at temperature in the range of 170–190°C. After aging the sections are inspected and packed before they are delivered to the customer for further fabrication and surface treatment, followed by joining and assembling into the finished component or product.

With a generic aluminum section (Fig. 10) some important features and characteristics of die design and productivity for aluminum extrusions will be demonstrated.

An order of 200 sections à 6 m of alloy AA6060 (Al-MgSi0.5) shall be produced in a 16 MN press with container diameter of 0.178 m and run out table length 42 m. The following typical process parameters can be calculated and controlled:

- The cross sectional area of the container is:

$$A_c = \frac{\pi}{4} 0.178^2 = 24.9 \times 10^{-3} [\text{m}^2]$$

- The cross sectional area of the extruded section is:

$$A_s = 0.084 \times 0.02 - 2 \times 0.028 \times 0.016 + \\ (0.003^2 - \pi \times 0.0015^2) \\ \frac{10}{4} = 0.437 \times 10^{-3} [\text{m}^2]$$

Fig. 10 A “generic” extruded aluminum section

- The reduction ratio can, thus, be calculated to:

$$R = \frac{A_c}{A_s} = \frac{24.885}{0.437} = 57$$

This is a reduction ratio within the acceptable range for a one hole die.

- The circumscribed diameter of the section is:

$$d = \sqrt{0.02^2 + 0.084^2} = 0.086[\text{m}]$$

This is well below the maximum recommended diameter of $0.9 \times 0.178 = 0.16[\text{m}]$.

- Special features of the section shape that should be noticed, are a hollow rectangular section with constant wall thickness, an outer tongue and an inner rib. Furthermore, the profile is symmetric about the horizontal axis.

Productivity and Cost

A number of aspects are important to consider for a customer who is to choose between the many different suppliers of aluminum profiles. As a great number of sections ought to and have to be designed and manufactured for only one product type, customer service stands out as particularly important. Furthermore, the supplier must of course be able to deliver the section requested within an agreed time limit and to the specified quality. If the profile geometry is fairly complicated or a very high strength alloy is chosen, some suppliers may fall out of the race, but for most profiles one may not be able to differ on these grounds alone. And in the end, thus, all usually comes down to money. The basic parameters in the extrusion business are the prices per meter or per kg extruded section. These measures are dependent on the choice of alloy and the geometry of the section, and one has to contact different suppliers in order to determine exact prices. These should not differ too much since there is an active market mechanism working. This mechanism will, however, also pressure the suppliers to continuously seek to increase productivity and cut costs. It is in the creative negotiations between the customer and the supplier that the right price is agreed upon as a consequence of a section design with

the right balance between requirements for functionality and the cost efficiency in the extrusion plant. Important parameters that determine the productivity and cost of the extruded section are:

- Length produced per press cycle.
- Length of end cuts that have to be scrapped.
- Number of cut lengths per billet.
- The discard weight per billet.
- Number of billets produced, i.e. gross weight delivered to the press.
- Net weight ordered.
- The dead cycle, i.e. the time between each press cycle.
- The ram speed.
- The acceleration time, i.e. the time to reach the full ram speed.
- Time for die change.
- The price of billet delivered at the press.
- Die cost.
- Production cost.
- Unpredicted press stop.
- Unpredicted quality scrap, i.e. the number of sections produced, which are not conforming with the required quality.

The production cost may be measured as cost per minute extrusion time spent. This measure contains all direct costs and man-hour costs in the plant, divided by the estimated availability of the press in minutes.

The following example is meant to illustrate a typical calculation of the cost per meter and cost per kg extruded profile. The calculations are meant to refer to the section in Fig. 10, and data from the example of the previous section is used.

- The gross material mass (weight) is first calculated. The sections are cut to lengths of 6 m, of which 6 may be produced from each billet. In addition the first and the last meter of the total section is assumed to be of inferior quality and therefore scrapped. The total section length produced in the press cycle is then:

$$6 \cdot 6 + 2 = 38[\text{m}]$$

The mass per meter section can be calculated from the cross-section area and the density:

$$0.437 \times 10^{-3} \times 2700 = 1.18 [\text{kg} / \text{m}]$$

The previously calculated data can be used to find the run out mass per billet:

$$1.18 \times 38 = 44.84 [\text{kg}]$$

The length of the billet is chosen so that the discard length is 0.02 m. As the container diameter is 0.178 m, the mass of the discard is:

$$\pi \times (0.178 / 2)^2 \times 0.02 \times 2700 = 1.34 [\text{kg}]$$

The total mass of each billet may be calculated to be:

$$44.84 + 1.34 = 46.18 [\text{m}]$$

In order to compensate for possible quality scrap of 6%, 12 more lengths than ordered are produced. The total number of cut lengths are then 212, and the corresponding number of billets is:

$$212 / 6 = 35.3$$

Hence, 36 billets must be ordered and the gross material mass will consequently be:

$$36 \times 46.18 = 1614 [\text{kg}]$$

- The net mass of the sections delivered to the customer is, however, only:

$$200 \times 6 \times 1.18 = 1416 [\text{kg}]$$

- The yield, which is the gross mass of the material divided by the delivered mass is then:

$$\frac{1416}{1614} = 0.877 = 87.7 [\%]$$

- The total production time should then be calculated.

The run out speed of the press for this particular alloy and geometry is found to be 36 m/min or 0.6 m/sec. The additional time spent pr charge on reaching the desired run out speed, the acceleration time, is found to be 7 sec. Since the length of the billet (38 m) is known, the total time of a press cycle can be calculated to be:

$$38 / 0.6 + 7 = 70 [\text{sec}]$$

The dead cycle time then has to be assessed. The time spent on cutting of the discard after extrusion,

inserting a new billet and performing the burb cycle is found to be 15 sec. If one expects no additional unexpected stops, one only has to add the time spent on changing the die prior to extrusion. For this particular press this is found to be 180 sec. The total production time without any unpredicted stops and delays is then:

$$(70 + 15)36 + 180 = 3240 [\text{sec}] = 54 [\text{min}] = 0.9 [\text{hr}]$$

- The productivity is viewed as the net mass delivered divided by the total extrusion time and can optimistically be calculated to be:

$$\frac{1416}{0.9} = 1573 [\text{kg} / \text{hr}]$$

- Finally a calculation of cost has to be performed.

The material cost of the billet is set to 1.5 US\$/kg. Production cost is in this example found to be 50 US\$/min and the die cost for the order is US\$ 2000. The total cost respectively without and with the die cost is then:

$$1.5 \times 1614 + 50 \times 54 = 5121 [\text{US\$}]$$

$$5121 + 2000 = 7121 [\text{US\$}]$$

The corresponding costs pr m section delivered can be calculated:

$$5121 / 1200 = 4.27 [\text{US\$} / \text{m}]$$

$$7121 / 1200 = 5.93 [\text{US\$} / \text{m}]$$

Finally, the cost pr kg delivered section is:

$$5121 / 1416 = 3.62 [\text{US\$} / \text{kg}]$$

$$7121 / 1200 = 5.03 [\text{US\$} / \text{kg}]$$

The same die can often be used in several production orders. If all die cost is placed on the first order, one can produce the next orders without any die cost. Maintenance cost of the die is included in the production costs.

Measures of Section Quality

Process Variability

The aluminum extrusion process is unique in the sense that it offers the possibility to produce almost ready to use profiles of high quality and with large functional freedom at a relatively low cost. The product quality, which in the very

end will be judged by the product's ability to satisfy customer demands, relies heavily on the restrictions imposed on design by the process itself. Purely geometrical considerations indicate that profile dimensions necessarily will be limited by the press capacity and size, and it is known that material flow also puts restrictions on both wall thickness and changes in such. However, product quality is probably to the largest extent affected by the mere variability in chemical composition, microstructure, geometrical dimensions, mechanical properties and surface finish over the length and width of the profile. Such variations are connected to the transient nature of the extrusion process and the difficulties to establish a system of measurement and control of important parameters during the press cycle. Changes in temperature, deformation history and material composition of the extruded profile will be encountered both during the course of a press cycle and from one billet to another. Furthermore, both production parameters and dies have to be changed in order to extrude different aluminum alloys due to the fact that both their metallurgical and thermomechanical properties may differ considerably. If attention is not paid to controlling the material flow in the factory, the production of profiles with uneven and thereby also inferior properties will ultimately lead to either the distribution of products of poor quality or to low productivity due to excessive scrapping. Therefore, most producers of aluminum profiles stress the use of house-keeping and have established routines for production of profiles of different alloys based on experience. However, in order to make proper use of such routines sufficiently reliable and consistent, measurements of production parameters such as temperatures and pressures have to be obtained. This task is not easily performed due to the noise inherent in the process.

Dimensional Variability

In order to make a direct assembly of extruded profiles possible, the characteristic dimensions of the product such as straightness, thickness, height, width, length and angles have to be made within sufficiently narrow tolerances. Dimensional variability is to a certain extent always existent and often in the order 0.25 mm on thin-walled profiles. Open or partly open profiles tend to experience larger variation than closed ones, whose die construction is more robust. Based on experience with when the process can be expected to be under control, tolerance on wall thickness is often set to be around 10% of the nominal measure. Measurement of profile dimensions is usually implemented as a standard procedure at extrusion plants.

Table 1 which is taken from the German standard DIN 17615, gives an indication of within which tolerances the open profile in Fig. 11a can be delivered. Thickness variations may be caused by the changing deflection and temperature of the die during a press cycle. Another cause of thickness variations is wear. In the case of large production series, dies are often bought from die manufacturers

Table 1 Tolerances on section thickness after DIN 17 615

Measure of thickness, s, from [mm]:	Measure of thickness to [mm]:	Allowed deviation[mm]:
–	1.5	±0.15
1.5	3	±0.20
3	6	±0.25
6	10	±0.30
10	15	±0.40
15	20	±0.50
20	30	±0.60
30	40	±0.70

with too narrow bearing surfaces as to compensate for future wear. Furthermore, dies are also produced within certain tolerances, although somewhat narrower than those of the profiles. As a result of both these factors, die changes may cause variation in profile geometry. A last reason for variation in wall thickness is the deformation of dies through fracture when extruding hollow profiles. This is caused by uneven loading, which very often is a result of flow imbalance and is most common when extruding alloys of higher flow resistance such as for instance the 7XXX-series. Fracture need not always immediately be fatal, and the presence of a crack may very well lead to a gradual reduction of the die strength and increasing deviation from nominal thickness. The presence of a crack combined with flow imbalance will also often result in thickness variations along a wall.

Variation in height and width of the profile may be due to variation in manufactured die dimensions or wear. However, larger deviations will be measured if profile walls are curved. In this case, tolerances are set with regard to the maximum curvature that can be accepted. The curving of profile walls is often a result of varying flow velocity across the profile, which again is due to variation in wall thickness and friction conditions in different parts of the outlet of the die. Table 2 shows tolerances with regard to curvature of walls in the profile given in Fig. 11b.

Prior to stretching operations profiles very often have a certain curvature, a warping, in the direction of extrusion Fig. 11c. This is often also a result of variations in flow velocity in the profile, but can be caused by the uneven cooling rates of walls with different thickness. DIN 17615 gives tolerances on the deviation from straightness as a function of length as given in Table 3 and Fig. 11c. Flow imbalance may also lead to twisting of the profile along the extrusion direction. Fig. 11d and Table 4 show that this deformation is often measured as a distance, v , which can be taken to be a function of both the length and the width of the profile.

Even though the height, width and thickness of a profile may be within tolerances, assembly may be hindered by deviations in angular measures as shown in Fig. 11e. Direct measurement of angles on the profile is most easily

Fig. 11 Measures of geometrical deviation: (a) Wall thickness; (b) Curvature of walls; (c) Profile warping; (d) Profile twisting; (e) Angular deviation

done with the help of electronic equipment, but is relatively time consuming in comparison with simpler mechanical methods. DIN 17615 proposes the use of the length was a measure of angular deviation and this can be taken as a function of the profile width as seen in Table 5.

Variability in Surface Properties

High surface quality is usually obtainable when extruding aluminum profiles, and the combination of a very even surface, outstanding optical properties and large corrosion resistance makes the use of aluminum preferable to for instance steel in many applications. However, surface quality is extremely dependent on die design, billet quality and extrusion practices in general, and a series of surface defects may develop if proper attention is not paid to controlling the process.^[7] Given the excessive noise in extrusion equipment, it is not always possible to sort out the

causes for defects, and very often several different error mechanisms may be operating simultaneously.

Corrosion properties are related to the content of different alloying elements, in particular Cu, and are therefore mostly dependent on the properties of the billet. However, by extruding with the wrong parameters changes in chemical composition, grain sizes and surface roughness may be unfavorable to corrosion properties.

Die lines and pick ups are common surface defects shown in Fig. 12a and b and give an indication that the profile surface is formed in the presence of hard and uneven attributes or particles in or around the bearing channel.

Rough and worn out dies or abrupt changes in bearing lengths may be the cause, but it may just as well be that oxide build-ups behind bearings or hard particles from the billet cause the defects. In the first case dies should either be polished and nitride^[8,9] or scrapped. Oxide build-ups behind bearings are often the result of a too small relief area (Fig. 13), and this phenomenon can be reduced by either increasing the relief or the use of nitrogen shrouding behind the bearings in order to avoid the oxidation. Hard particles in the extruded sections often originate from oxidized and even dirty material on the billet surface even when performing direct extrusion. In flow of material from billet surface will take place if the container temperature is too high, causing a low yield resistance and easy flow of surface material.^[10] In flow to the bearing channel may also take place if a too large profile is extruded or the container is misaligned so that surface material may flow directly out of the bearing channel. Hard particles may also exist in the interior of the billet if it is not properly homogenized, or, in the case of 6061 and 6063 alloys, the iron content is high so that AlFeSi particles are formed. As to complicate matters

**Fig. 12** Visualization of various surface defects

Fig. 13 Detail from a porthole die: An area of relief may be found behind the bearings

further, research has shown that the presence of die lines will be heavily dependent on the size of the bearing angles when defects are caused by AlFeSi particles.

The profile surface may contain blisters as shown in Fig. 12c, which may be inclusions of air, oxides or even oil. Such blisters degrade surface appearance and mechanical properties, and when the profile is cooled, blisters may also crack, creating a distinct sound and causing open holes in the profile surface. They may be a result of inflow of material from the surface of the billet or inclusions that are already contained in the interior of the billet prior to extrusion. However, blisters containing air, are often caused by air trapped in the container due to too fast upsetting or air trapped in hollow porthole dies prior to extrusion. Hence, they may very often be found close to the forward part of the profile or charge welds. When extruding light metals, lubricants are not used. Contamination of oil must therefore be avoided. Lamination is also a result of contamination and should be avoided in order to preserve both mechanical strength and in some cases also appearance. This phenomenon may be a result of inflow of oxidized and contaminated material from the surface or from the charge weld.

Sometimes, when studying an extruded aluminum profile, areas of different shades of gray color may be detected. This surface defect is called structural streaking and is a result of varying reflective properties across the surface. While streaking seldom will be a reason for scrapping the material, efforts are often made to extrude under conditions that give even optical properties. This is especially the case if surface treatments such as etching and/or anodizing are to be employed since these processes tend to accentuate streaking. Streaking is a result of variations in grain size and grain orientation of the finished product, and three somewhat different types have been identified. These are streaks caused by variations in bearing surfaces, variation in temperature, amount of hot work and recrystallization. However, as streaking in general is a result of the whole thermo-mechanical and metallurgical treatment of the material, it is not always possible to differ between the different types. So-called bearing

streaks are often due to uneven bearing surfaces, having created depressions in the profile surface. Hence, light is reflected in different planes and streaks are only visible when viewed from specific directions. A type of combined bearing and grain size streaking is caused by sudden shifts in bearing lengths due to varying profile thickness. Apart from leading to problems connected to filling, such a die design will give abrupt changes in grain sizes and orientations and also reflective properties over short distances in the profile. Furthermore, as the amount of heating is varying, the temperatures and the degree of recrystallization may also be expected to be changing. Oxide streaks can be recognized as dark streaking areas of varying width and intensity on etched or anodized parts. The presence of such streaks is linked to the inflow of oxidized material from the billet surface to the bearing channel. Oxide streaks will be avoided if inflow is hindered. In general, structural streaking will be less of a problem if material in all parts of the profile cross-section undergoes much of the same thermo-mechanical loading. Furthermore, experience has shown that a minimum degree of choke on bearings should be sought in order to reduce variation in reflective properties.

Cracking or tearing of the extruded profile is experienced when process control is lacking. If the temperature of the extruded metal on the bearings is too high as a result of preheating of billet or high extrusion rate, partial melting of Mg_2Si particles will take place.^[11] Thus, cracking of profile surface or so-called hot tearing may be the result. If cracks develop in the die or pick-ups are created through insufficient clearance behind bearings, edges may be torn.

Surface quality is often also reduced through scratches and gouges asserted in material handling processes on the run-out table, lift-overs, walking beams, saw tables or in stations for packaging and stacking. Efforts must be made so that profiles are not damaged in transport. Great emphasis has been laid on establishing best practice in handling materials and on securing that equipment used can cause minimal damage. However, due to the large variability in profile geometry and the great demands on material handling, many operations must be performed manually at high costs.

APPLICATIONS, ALLOY SELECTION AND DESIGN CONSIDERATIONS

By developing products out of materials found in nature mankind has managed to differentiate itself from the animals. The fact that historians have tended to denote periods by the names of the materials found in the tools and other equipment of the times, indicates that one assesses the use of materials to be of prime importance to human life. Today, one recognizes the stone, bronze and iron age, but not surprisingly, when dealing with the present, the determination of the material with the greatest importance

turns out to be harder. Some emphasize that relatively new materials such as plastics are omnipresent and have brought enormous changes to human life over the last decades while others maintain that the increasing use of computers marks the entrance to the silicon age. However, the fact still remains that iron in the form of steel even today by far is the most favored material for most applications. The strongest contender of the metals is aluminum, but as for volumes produced, steel is about 20 times larger. So, in spite of the several industrial revolutions that have taken place in last century, it may still be claimed that the contemporary period is the one that was allegedly introduced by the Hittite development of iron around 1300 BC.^[12]

Product Development

Innovative thinking is maybe the one most important virtue of a designer, but if ideas are to be transformed to innovations, proper use of knowledge of and experience with both design principles, processes and materials is mandatory. In fact, modern product developers often stress that focus must not be placed on the mere functional properties of the product and the ability of the product to satisfy consumer's demands, but also on the chain of processes from raw material to components, joining, surface treatment and assembly. Obviously, a quality product will not only be satisfactory to the user, but also to the producer in that it creates possibility to generate a surplus.

Three aspects are of equally great importance when creating a new component that is to satisfy the user's notion of quality. In Fig. 14 product development is given as a combination of function, production and material. The functional side is linked to the transforming of new concepts of for instance physical or structural origin to products that are of lasting value to the user. The goal for the

production system is to establish processes and routines so that new products can be manufactured within calculated costs and time limits. When developing a new product one should attempt to make use of possibilities offered by manufacturing systems to forward functionality rather than letting the system impose restrictions or additional cost. Obviously, when having decided on a concept, the most optimal production process should always be sought. However, one should also bear in mind that manufacturing processes automatically offer new degrees of functionality to the product. Therefore, the alternative candidates of production methods should be evaluated at a very early stage in the design process.

Another fundamental aspect of product development is the use of materials. Traditional use of materials is limited to choosing on the basis of only certain tabulated data such as yield limit or tensile strength and, in some cases, corrosion properties, and often due to limited knowledge of alternative materials, steel is the most favored material for most constructional applications. However, materials should not only be chosen, but also designed so that both functional demands are satisfied and so that production is simplified. For a long time, more advanced users of materials, such as the aircraft industry, have realized that optimal solutions only can be reached by making use of the whole specter of new materials and by obtaining knowledge about and manipulating the microstructure. In this way, the design process has been brought all the way down to atomic level, thus spanning more than ten orders of magnitude (Fig. 14). Over the last decade it has become apparent that thorough knowledge of material properties is prerequisite in almost all design work and that the traditional practice neither is in accordance with customers demands nor international standards.

As shown in Fig. 14 product innovation is taking place in parallel to innovation connected to the properties of

Fig. 14 The Life-Cycle-View (LCV) of a component

process and material. New or improved materials or processes will increase possibilities to create products with new functions or improve older products. As shown, a large number of fields of research will in one way or another contribute to the development of new and better products. As the possibility to improve products increases, so does consumer demands to quality. While factories earlier could produce and sell enormous numbers of standardized goods with often inferior quality, today's consumers demand products with which they can identify themselves, and which are virtually perfect. An example of enterprises which meet such demands each day are of course those of the automotive industry.

Furthermore, one has over the last couple of decades witnessed an increasing consciousness of environmental protection and sustainability, and in the very recent years, this emphasis has not only focused attention to cleaner production, health and safety within the individual production plant, but also on the product life cycle and loop closing of products, components and materials. A consequence of the interest in including industrial ecology and eco design into industrial practice is that important new concepts and methods are under development.^[13] They are Life Cycle Assessment (LCA), Life Cycle Cost (LCC), eco-efficiency

and eco-effectiveness. It is not possible to go into these concepts here, but the combined ecologic and economic life cycle performance of products and processes will probably be among the more important features of successful products and processes in the years ahead. Thus, it seems natural that the designer must think more in terms of establishing life cycle systems than isolated products. Innovations for exploiting the life cycle merits of aluminum alloys should be the hallmark of aluminum components and structures. Figure 14 shows a Life Cycle View (LCV) of a component, placed in a life cycle time scale (abscissa) and an order of size scale (ordinate). Here the interactions between the details and the whole are visualized, so that critical success parameters can be identified more easily. Very often one sees that successful products are a result of combined innovations of process, material, product and production.

In the UNEP-manual^[14] van Hamel has designed a so-called "Ecodesign Strategy Wheel" (ESW) as a tool to formulate strategies for improvements of economic and ecological performance of products, processes and practice, both in a short term and in a long term perspective, Fig. 15. An existing product is used as a present time reference of improvement (improved eco-efficiency) and

Fig. 15 The Ecodesign Strategy Wheel (ESW) with (a) reference product profile; (b) Short term development strategy; (c) Long term development strategy

a scenario of a possible future sustainable society as the goal to strive for (measure of eco-effectiveness). It may be useful to see the connection between the Figs. 14 and 15. The Life Cycle View (LCV) can be transformed into the Ecodesign Strategy Wheel (ESW) by bending the LCV into a cylinder and view it from above, Fig. 16.

As can clearly be seen, the work of the product developer is both getting increasingly difficult and challenging, and greater demands are placed on his or her ability to master all aspects of the product development process. Innovative thinking and a well documented understanding of customer's needs will of course still be at the center of attention, but the model discussed may be an important tool when establishing an integrated method of product development, which in any way is bound to take function, production and material aspects into account.

Table 6 gives an overview of extrusion based systems and components and the generic alloy selection for the different applications areas. With a generic alloy selection here one understands an alloy, generally used for the specific application, which will be available in most markets and with properties best documented. It should then be the alloy first selected by the designer, and only be changed if special combinations of properties, not found in the generic alloys, is needed. It is then important to contact potential suppliers of the section to ensure that the alternative alloy is available to acceptable price and with properties documented. A short description of some typical products in these main application areas are given below. It is recommended, however, to actively collect information brochures and inspiration material from aluminum producers, extrusion plants and final product manufacturers as basis for understanding the rich diversity of design solutions based on extruded aluminum rods, tube and sections that is possible.^[15]

Fig. 16 Two aspects of life cycle thinking

Designing with Aluminum Sections

Even though one may find that the ideal material to be used for a product is aluminum and that manufacturing should take place in the form of extrusion of profiles, there is still great freedom with regard to the functions that the product could fulfil.^[16] Aluminum profiles are used in a number of applications, and the following five groups may be identified:

- Buildings, architecture and furniture.
- Structural.
- Transport.
- Heat exchangers and electrical conductors.
- Durables and Mechatronics.

A short listing of some typical products in these main application areas is given in Table 6. Although profiles are produced as long beams, and thus, originally only contain variations in two dimensions, forming or cutting processes may be used to modify the product so that parts with variations in all three directions may be obtained. Furthermore, as a large number of alloys with a specter of properties have been developed, the choice of aluminum puts very few limitations on design. It is recommended to actively collect information brochures and inspiration material from aluminum producers, extrusion plants and final product manufacturers as basis for understanding the rich diversity of design solutions based on extruded aluminum rods, tube and sections that is possible.

Aluminum is at the present undoubtedly one of the most popular engineering materials. Its popularity is mirrored by the fact that the metal, in terms of volumes produced, is second only to steel and as large as all other non-ferrous metals combined even though it was first introduced only about 100 years ago. The reason for the material's enormous success lies in its thermal, mechanical and electrical properties, or in short in its microstructure. Aluminum is light, but some of its alloys are able to compete with comparable steel alloys in terms of both yield limit and tensile strength. At the same time much less effort is needed in hot forming of aluminum than of steel with the same yield limit at room temperature. This is due to the fact that aluminum has a rather low melting point and that hardening processes, such as aging, are taking place. Furthermore, even though Young's modulus of aluminum is only 1/3 of the modulus of steel, aluminum beams can be stiffer than steel beams of the same weight due to the fact that aluminum is lighter than steel. The ratio of Young's modulus to weight is about the same for the two materials, but such a comparison is unfair to aluminum because the lower density offers the opportunity to place material at farther from the neutral axis, thus creating larger momentum. Aluminum is also a very efficient conductor of both heat and electricity. Because an undamaged and untreated surface reflects almost 90% of visible incoming light, aluminum exposed to direct illumination will be

Table 6 Applications of extruded aluminum rod, tube and sections

Main process	Systems components	Generic alloys	Selected applications				
			Building architectural furniture	Welded structural	Transport	Heat exchangers electrical conductors	Durables mechatronics
HOT EXTRUSION OF ALUMINUM	Systems of sections	AA6060 AA6063	windows and doors shelves shower cabinets		utility vehicles	conductors cables multiport tubes	housingss
	Structural sections	AA6082 AA6061	building structures scaffolding	bridges	utility vehicles		ladders stairs
	Bended and locally formed sections	AA6060 AA6063 AA6082	furniture ship windows frames	space frames	bumpers seating spaceframe	bended tubing in heat exchangers	
*ROD	Components manufactured by shearing, drilling, milling, etc	AA6060 AA6063	hinges building elements			cooling elements	tooling hosing multifunctional components
*OPEN SECTION	Cold drawn tubes	AA3103			radiators air conditioning systems fuel lines	air conditioning systems heating equipment	
*TUBE	Coldforged components from rod, tube and section	AA6351			steering column		
*HOLLOW SECTION	Hot forged components from rod	AA7075			air craft components		

extremely resistant to heating. This makes the material useful for structural purposes. If, however, aluminum attains higher temperatures elongation will be larger although thermal stresses will be smaller, a result of aluminum's higher thermal coefficient of elongation but lower elastic modulus. One of the appealing characteristics of many aluminum alloys is a high corrosion resistance.

Over the last 30 years questions have been raised as to whether the production of aluminum is in accordance with the principles of a sustainable development and related thinking. The major concern has been that although aluminum is the most common metal on earth, so called high-grade deposits of bauxite are to a certain extent limited. Another objection has been related to the large amounts of energy needed to produce primary aluminum. The aluminum industry has responded by developing LCAs and by modifying and improving the Bayer process so that it accepts bauxite that was formerly assessed as low-grade. However, it turns out that recycling of aluminum is a result

of market mechanisms and the properties of aluminum and not of state legislation as is the case for plastic materials and to a certain extent steel.^[17] The fact that a much larger amount of energy is needed to produce primary aluminum from raw material than secondary metal through remelting, makes efforts invested in recycling highly profitable. One is today talking about an aluminum bank, which exchanges metal with the market by selling finished products and buying scrap. A closed loop has long ago been established. At present, about 30% of the material going into new components is of secondary kind. The driving force in the material bank is of course energy, usually supplied by hydroelectric power plants. Had it not been for human interference aluminum in the form of pure metal would be non-existent in nature as the spontaneous process of oxidation through the times have degraded all material, leaving only Al_2O_3 . Large amounts of energy are needed to extract metal from its oxide. Hence, aluminum metal might be looked upon as an energy investment. As questions are

raised regarding the soundness of using energy producing metal one has to assess the alternatives, that is merely comparing energy investments. Much smaller energy investments are done when producing steel, but one might say that the oxide layer of aluminum represents a more secure bank than steel does. However, by employing light metals in, for instance, the transport sector one can obtain reductions in fuel consumption, which is the equivalent of being paid back on the initial energy investment. In structural applications the payback on the energy investment can not so easily be detected, but if the need for maintenance or use of materials can be reduced, energy is eventually saved. This analysis should be an integrated part of the LCA and product development process, and the designer should always ask whether energy can be gained by applying aluminum in a construction. In the aircraft industry a conclusion on this question was reached, if not formally, but at least intuitively, already in the 1920 by the construction of the world's first aluminum aircraft Ju-7. Today, airframes consist about 70–80% by weight of aluminum, of which a large part is in the form of profiles. In other parts of the transport industry demands for lightweight have until recently not been that strict, but as environmental issues are pressed and competition is increasing both with regard to prices and velocity, new materials and concepts are brought forward. Examples of just this are the employment of aluminum in high-speed trains such as the French TGV duplex, the German Maglev system and the Japanese superconducting Maglev system. Changes are even taking place within shipping, which traditionally has been viewed as a notoriously conservative enterprise. Passenger transport have already for some time been carried out by aluminum-intensive fast ferries, and so-called high speed surface effect ships for transport of goods are also under development. As aluminum frames are being employed to a greater extent in both buses and commercial vehicles, the next breakthrough is expected to take place in the automotive industry. However, even though LCAs are performed in this industry, consumers still tend to look more at the initial cost than costs related to use. Hence, the lightweight solutions are not sought as vigorously as in the other branches of transport industry. New cars contain about 70 kg of aluminum parts, and smaller production series of more expensive cars have been made with so-called space-frames of aluminum. Such frames comprise the structural elements of the car.

In connection with material forming, one should notice that aluminum is unique in the sense that it can be extruded to a beam with a cross section of almost any form, open or hollow. Due to the large forces that are generated when extruding steel, geometrical forms must be kept simple and only smaller reductions in sizes of cross sections can be obtained. Another light metal, of which some use has been made in for instance the automotive industry, magnesium, is less extrudable due to its hexagonal close packed structure.

A world of new opportunities with regard to functionality and form arises when designing with aluminum profiles. In all there are very few limitations to the forms that can be produced by extrusion of aluminum, the largest problem being that variations in geometrical features are only two-dimensional in nature. However, beams may be given different lengths and profiles can also be altered by the processes of bending and hydroforming. Therefore, fully three-dimensional structures as the space-frame of a car or a window frame may be designed. The case in the following chapter gives an example of a simpler but successful design that managed not only to satisfy the original demands imposed on functionality, but also to incorporate other useful functions. This is a result of the freedom that aluminum, as a light metal, and extrusion, as a versatile process, offer. The most serious restrictions encountered in the design process, are caused by designer's experience with steel constructions. Steel products comparable to extruded profiles are manufactured in standardized forms and dimensions, and a steel design will often be an assembly of a series of such parts. Machining operations must be applied in order to impose modifications. Even though aluminum profiles of standard shapes are sold, it is usually better to think in terms of new profile designs better suited for the application. Extrusion tools are relatively cheap to produce. The prices of open dies can be expected to range from \$1000 to \$2000 while hollow dies will be more expensive, from \$1500 to \$4000. Tools for complicated profiles will naturally be manufactured at higher costs.

However, if profiles can be made so that machining, welding and assembly operations can be avoided, investments in dies may be worthwhile even for smaller production series. Hence, the development of tailor-made products may prove to be cheaper than mass production of standardized products with simple shape. This fact indicates that the extrusion process is well adapted to consumer's demands and their notion of quality.

As for functions that can be integrated in a profile, limitations are only imposed by the human imagination. An example of a function that is in common use is the locking mechanisms, which simplifies assembly and reduces the number of parts needed in the design. Generally, such a solution also reduces the cost of the product and is often necessary to secure competitiveness. Figure 17 displays examples of various locking devices. The basis for all these is aluminum relatively low modulus of elasticity.

Cast and extruded aluminum parts complement each other in most applications, but if both processing methods can be used to produce a part, extruded products are usually preferred. Tools needed for casting operations are more expensive than dies, and the production rates of the two processes are not comparable. This indicates that wherever possible, solutions including profiles should be sought. Another reason for choosing profiles to cast products is that wrought alloys usually have better mechanical properties than cast alloys. This is partly due to defects

Fig. 17 Joining of sections by the use of snap solutions

created during casting and partly to the fact that cast alloys contain large amounts of silicon and copper, which cause a heterogeneous structure with brittle secondary faces. In general cast alloys have lower elongation and strength, especially in fatigue. The progress in improving casting alloys and controlling the casting process in the recent years, however, has been impressive, both for aluminum and magnesium alloys, as well as for steel. The designer should therefore take care to make process selection based on the present state of the art.

Alloy development is the subject of continuous research. By systematically varying the content of different alloying elements improvements in properties such as tensile strength, ductility, fracture strength, fatigue strength, corrosion resistance and formability are sought. At present about 350 wrought alloys are commercially available, but not all of these are interesting from a designer's point of view. While the aluminum industry must continuously seek alloys with improved properties, the designer should

concentrate on a group of so-called generic alloys. On Table 6 an overview of extrusion based systems, components and the generic alloy selection for the different applications areas is given. A generic alloy selection is taken to be an alloy, which is generally used for the specific application, is available in most markets and has properties that can be expected to be thoroughly documented. It should be the alloy preferred by the designer, and the choice should only be changed if special combinations of properties, not found in the generic alloys, are needed. It is important to contact potential suppliers of the section to ensure that the alternative alloy is available to acceptable price and with properties documented. When choosing particular alloys one must also remember that an alloy, which is optimal with regard to all properties, does not exist. Alloys with high yield and tensile strengths are usually harder to extrude, thus resulting in lower production rates (Fig. 18), higher prices and limitations on product geometry. Thin-walled sections of high strength material are for instance

Fig. 18 Relation between material strength, minimum wall thickness and extrudability/press velocity. The results apply only to a section with a specific geometry, but similar curves may be established for all profiles

not extruded easily. Some alloys are also in possession of relatively low corrosion resistance even though mechanical strength may be high. The group of generic alloys should contain elements that can be used for most applications.

Profiles containing precipitation hardening alloys are relatively easily formed, but gain high strength after heat treatment. This explains why about 80% of all extruded products are made of the 6XXX-series of alloys. Members of this group can gain from medium to high strengths. High extrusion speeds and very high productivity can be obtained when extruding the alloys with medium strength. 6XXX-alloys are generally relatively corrosion resistant, but this property is both dependent on the chemical composition and the thermal treatment the material has undergone. While the alloy 6060 contains limited amounts of magnesium and silicon and is of only medium strength, tensile strength the high alloy metal 6082 has a tensile strength of about 340 MPa at room temperature in the T6-condition.

For sections that are not carrying loads the 6XXX-series is the natural choice. In such cases even the 3XXX and 1XXX may be applied as these alloys are in possession of superior corrosion and conduction properties. If a product is designed to carry loads, different 6XXX-alloys may still represent alternatives, but one should always evaluate whether it is profitable to reduce weight by using alloys of higher strength. It has been found that both in structural applications and in many areas of transport designing with the 6XXX-series is most rational due to the low cost of extrusion. In some branches of transportation such as aviation and of course space flight the use of material with the highest strengths is mandatory. Production costs connected to extrusion will be substantial, but by decreasing weight or increasing the load capacity these expenses are soon covered.

The strengthening mechanism of the 7XXX-series is also precipitation hardening, and as for load capacity and strength these alloys represent the next step on the ladder. In aerospace construction 7075 is a preferred alloy. The automotive industry has also made use of several of the 7XXX-alloys. However, the fact that dies will experience more wear and that extrusion rates will be lower for higher strength metals applies also to this group and is limiting its usefulness in most applications. The low extrusion rates will not only be a result of the material's higher flow resistance, but also of a somewhat lower melting point of some phases. Besides, if the quench rate after extrusion is low, corrosion resistance will generally be unsatisfactory. Larger contents of copper are causing the high strength/low extrudability as well as the degraded corrosion properties.

The 2XXX-series has traditionally also been used in aerospace construction and shows extremely good damage tolerance. It has both high fracture toughness and high resistance to fatigue crack propagation. As the 2XXX-alloys contain much copper, they tend to show low corrosion resistance. Important alloys are the 2X24^[18] and

the 2X19. The 2020 and 2090 alloys are so-called lithium alloys. For every weight percent of lithium added, the elastic modulus of the material is increased by 6% and the density lowered 3%. Hence, very stiff and light aluminum constructions can be developed by the application of lithium alloys. Use has been made of such materials both in fighter aircraft and space shuttles, but only to a limited extent in commercial aircraft. Another important property of the 2XXX-series is that high strength can be obtained at relatively high temperatures. This, however, complicates extrusion, and products made of 2XXX-alloys are today mainly manufactured in other forming processes.

Limitations on Section Design

Even though one should focus on possibilities when designing with extruded profiles, one is sooner or later bound to encounter the limitations that the process imposes. Evidently these limits are dependent on both the process equipment and practice and on the choice of material. If the process is not properly controlled or the design and choice of material is not in accordance with the choice of process, poor product quality will unavoidably be the final result. In the last part of the second section of this chapter some of the symptoms of low product quality were discussed, and their cause has and will be further discussed. Suppliers of extruded profiles have established general design rules, which can be used to secure that a design is in harmony with the process. Some of these are general in character, while other are referring to specific dimensions and are necessarily dependent both on material and process equipment. However, apart from restrictions on the size of the largest sections produced, there are seldom any absolute limitations. Very few profiles may prove to be impossible to manufacture, but there is always the danger that the quality or the price of the product may be unsatisfactory to the consumer. In order to develop a quality product, the designer must try reach production friendly solutions through discussions with experienced people at an extrusion plant.

If full freedom in designing a functional product is to be obtained, no limitations should be placed on form. However, as will be understood from a study of flow patterns, a key word in relation to the process of extrusion is symmetry. Asymmetric profiles cause flow imbalance and necessitate complicated die design. Flow velocity in the cross-section must be controlled, and this often leads to low extrusion rates. Furthermore, as dies may experience uneven loading, there is an increased danger of fracture and unstable tools, especially when extruding higher strength alloys. Asymmetric profiles may also cause thermal gradients in both die and profile during cooling. Hence, not all parts of the profile will be given the same thermomechanical treatment, and the result of this is a loss of control with metallurgical processes in a product with large variation in both microstructure and properties. A last problem connected to

asymmetric profiles is that possible bending and stretching operations may be more complicated to perform. Examples of deviations from symmetry are given in Fig. 19. The mass distribution over the profile cross section should not be uneven. Large ratios between the thickest and thinnest walls in a profile may also be difficult to handle, and large eccentric hollows also cause an unwanted flow pattern.

Naturally strict limitations exist with regard to the size of the profile, and specific numerical values must be sought from the producer. If the profile has a too large circumference circle diameter, that is the smallest circle surrounding the profile, problems connected to inflow of material from the billet surface may arise. Furthermore, extrusion of large profiles is often synonymous with very open die designs, which usually are weakly supported, and in the case of hollow profiles, larger forces on the mandrel of the die are generated. The result will be larger dimensional variations and also poorer surface quality due to either die lines or streaking. On the other hand profiles with too small dimensions give larger press ratios. In this case the press may not be able to supply the needed force to generate the profile. The solution is then often to press several strands simultaneously in order to increase productivity (Fig. 5).

Simplicity is another key word in almost all areas of production. This certainly also applies to the extrusion process even though its largest virtue maybe the complex profiles it offers. Both hollow profiles and profiles with large tongues tend to increase the complexity of the production, and thus should in fact be avoided if possible. Dies, which are made for such profiles, are more complex and necessarily also more expensive. However, the largest problem is that they tend to generate larger forces due to the restrictions they impose on flow, and that at the same time their weaker design gives them a lower load capacity. Die breakage and large deflections are usually the results. Dimensional variability and poor surface quality can usually be expected in such cases. The solution may often be

that tongues are made with smaller length to width ratios so that they can be properly supported and that hollow profiles are made as two open sections, which later can be assembled.

A lot of special forms and features are usually included in the extruded profile so that the product is able to perform a large number of functions. However, the addition of even small attributes may lead to large changes in both productivity and product quality, and one should always assess whether a feature is necessary and whether it could be made in a more process friendly manner. Examples of features that are difficult to handle are:

- Sharp corners may in some cases cause incomplete filling and in others tearing (Fig. 19). Besides, crack initiation and growth usually takes place in the parts of the die where sharp angles exist. Hence corners should always be rounded. The smallest radiuses that should be used are around 0.4–1.0 mm. Only for special purposes may a radius of 0.2 mm be applied.
- Sudden steps in wall thickness and thus also the bearing lengths of the die should be avoided (Fig. 19). Two related types of flow problems will be the result of such changes. On the one hand, complete filling of the sharp corners around steps in wall thickness will be hard to perform if bearings are not carefully designed. On the other hand, streaking may be the result of microstructural differences caused by the abrupt change in the conditions of deformation and cooling from areas of large to small thickness. The solution to this problem is a gradual change from thicker to thinner regions. If this proves impossible, the streaking can be made less appalling simply by constructing a notch that may mark a natural border between thicker and thinner regions. However, this does nothing to decrease the problems connected to varying mechanical properties, and may in turn cause a larger flow resistance.

Fig. 19 An extruded profile with a complex geometry

- At a certain point extrusion of thin-walled parts will always represent a problem. For such parts friction forces are high, and flow speed is hard to control. The result may be incomplete filling of some parts of the cross-section and of course a need for greater extrusion force. If internal walls are too thin (Fig. 19), complete filling is even harder to obtain, and pressures in the welding chamber may not be sufficiently high to secure a proper weld. Weak or non-existent seam welds are both disastrous to profile quality and hard to detect. Hence, internal thin walls should be avoided. Often it may be better to use larger wall thickness to secure filling even though material cost increases. Another problem with internal walls is that the whole die concept becomes weaker and that there is a greater danger of die breakage.
- Details generally cause problems connected to flow balance and friction heating, and as a result, production rates are limited (Fig. 19). Furthermore, tearing of the surface and incomplete filling may be additional problems. Details that do not fill any functional purpose should therefore not be added to a profile. Obviously, one should try to design details sufficiently thick and not too long. At the same time corners must be rounded. One also ought to bear in mind that internal details are usually more problematic than external.

Apart from these limitations on form connected to the process, there are a lot of others that are related to the use of the product. One such may for instance be that corrosion should be prevented by avoiding geometry that can lead to the gathering of water in the profile. Whereas designers who are not accustomed to working with aluminum profiles, easily may overlook one of the many restrictions imposed by both process and material aspects, the experienced ones will develop a product which integrates most of the aspects previously mentioned. However, to all designers, the establishment of a method of design that systematically incorporates the treatment of all aspects of importance, is a necessity when applying aluminum for constructional purposes.

Case: Helicopter Landing Deck on Offshore Platform

Usually aluminum profiles are most competitive in applications where they must be designed to fulfil many functions at the same time. Helicopter decks on offshore platforms is such an application. On platforms, such as the tension leg platform, Snorre, in the North Sea, weight aspects are often critical. Furthermore, the corrosion properties of the material must be outstanding, as weather conditions are often very harsh. Originally, helicopter decks were made out of steel plates that were welded together and supported by traditional steel beams, but the solution was by far optimal. The construction has gradually been modified, and

the aluminum deck in use today is about 60% lighter than the original one. By using profiles, large design flexibility has also been obtained, and many more functions have been implemented in the construction. It was expected that the surface construction of the helicopter deck should perform the following functions:

- Carry structural loads.
- Carry concentrated loads.
- Carry torsion loads.
- Be simple to assemble.
- Prevent slipping.
- Lead away petrol and rain water.
- Allow circulation of air in order to prevent crevice corrosion.
- Lead fire extinguisher fluid.
- Lead deicing cables.

Demands were that the helicopter deck had to be designed so that it could easily be fitted to the platform, and that it was constructed in accordance with regulations and standards. Evaluation criteria would be related to the weight and the strength of the construction and to corrosion properties. Furthermore, as almost always, the product had to be evaluated on the basis of life cycle cost.

The original steel construction did not have the desired functionality, but it was able to carry the specified loads. Hence, when the first modifications in aluminum were made, the design was not altered but dimensions were changed to suit the properties of aluminum better. Of course modifications to dimensions can be done in a number of ways. If the length of the rung is kept constant the thickness of the profile may be increased about three times, resulting in a profile of the same weight and only marginally increased stiffness. A simple calculation can be made to show the effect of a uniform thickening of the whole profile. The geometry is shown in Fig. 20. The moment of inertia can be calculated to be:

$$I_x = \frac{1}{12}((8h_1^3 + 12h_1^2h_2 + 6h_1h_2^2) \times w_1 - h_2^3w_2) \quad (1)$$

For the steel beam both h_1 and w_2 can be set to t , and h_2 and w_1 to l . This gives a moment of inertia equal to:

$$I_x^s = \frac{1}{12}(5tl^3 + 12t^2l^2 + 8t^3l) \quad (2)$$

Since the density of aluminum is about $\frac{1}{3}$ that of steel the dimensions h_1 and w_2 may be set to $3t$. This gives a moment of inertia of:

$$I_x^a = \frac{1}{12}(15tl^3 + 108t^2l^2 + 216t^3l) \quad (3)$$

The stiffnesses that are obtained for steel and aluminum are respectively:

Fig. 20 Simple I-beam originally in use in helicopter decks and manufactured through the processes of rolling and welding

$$W_x^S = \frac{E}{12} (15tl^3 + 36t^2l^2 + 24t^3l) \quad (4)$$

$$W_x^A = \frac{E}{12} (15tl^3 + 108t^2l^2 + 216t^3l) \quad (5)$$

E represents the elastic modulus of aluminum. Since l is much greater than t the first term will be dominant, and it can be seen that no large gains can be achieved by using aluminum in this way. However, a much larger increase in stiffness can be obtained if the rungs are made slimmer and taller and the flanges are designed thicker. If for instance h_2 and b_1 are set to $3l$ while the thickness of both flanges, and if the rungs keep the thickness t , the profile can gain a stiffness of:

$$W_x^A = \frac{E}{12} (135tl^3 + 108t^2l^2 + 24t^3l) \quad (6)$$

Clearly, by intelligent design bending stiffness may be increased enormously. However, the calculations just made are extreme cases. Problems would arise if the last cross-section were to be used, both because the flanges could not carry the possible concentrated forces and because rotations due to torsion of such a section would be large. The torsion momentum would depend on the thickness of the section in the third power. The torsion stiffness of the original steel section will be about one third of that of the extreme aluminum section. The aluminum profile, however, will be more severely loaded due to the long flanges and rungs. The optimal cross section of the type given in Fig. 20 could be reached by maximizing both bending and torsion stiffness with respect to the different measures. Such an analysis reveals that the use of aluminum profiles generally is preferable to the use of steel. However, when constructing with profiles even larger

gains in torsion stiffness can be made by applying hollow profiles. By turning to extruded profiles much freedom in functionality can be obtained, and a positive side effect of this is that the profile may be given such a form that all the desired functions mentioned above can be fulfilled. Different stages in the development process are shown in Fig. 21. The same figure shows the aluminum profile which is currently in use in platform decks in the North Sea.

THE EXTRUSION PROCESS

Describing the Conditions of Flow

Traditionally, advances in extrusion technology have come as a result of experimenting. In fact, as the process has until recently been viewed as too complex to be understood in its entirety, the key to success in the extrusion business has been the establishment of a system of best practice based on experience gained through trial and error. Experiments are still expected to be an important element in establishing knowledge of fundamental aspects, and due to the large amount of noise in data received from extrusion presses, one can hardly expect to avoid errors, from which insight should be gained. However, the impetus for discovering and improving methods for predicting results a priori is large. Experiments are usually expensive and time-consuming, and practices such as die correction, which even to this day to a large extent is based on the experience of the workman, will most probably neither satisfy demands to productivity nor quality in terms of for instance dimensional variability. Hence, research is today focused on the development of mathematical methods that are able to describe and thereby also predict both the macroscopic and microscopic changes taking place during deformation. In this way the manufacture of dies and the control of process parameters can be performed in such a manner that profiles will be produced within the narrowest tolerances and to a low cost. As extrusion is a process taking place in the presence of large deformations and at relatively high temperatures an establishment of such a mathematical fundament is both a complicated and to a large extent a multidisciplinary task. A unified approach must link knowledge of metallurgical processes at high temperatures and strain rates with the continuum theories of rheology^[19] or plasticity. Furthermore, as analytical results can hardly be obtained, the development of effective numerical procedures will be of greatest importance. Naturally, a thorough understanding and experience with all aspects of the process will also be a prerequisite for establishing a model.

Experimental Studies of Flow

Hot extrusion of aluminum is performed at temperatures from about 450°C to something above 600°C, depending

Fig. 21 The profile development process and the profile in use today

on the melting point of the alloy. At these temperatures the material has a relatively low resistance against dislocation movement, and shear deformation will therefore be initiated when the extrusion force reaches a certain limit. The material then starts flowing out of the die and will permanently change shape. If homogenous deformation had taken place, the longitudinal logarithmic strain would be equal to $\ln(R)$. Strains of magnitude $\epsilon_z = 4$ are therefore not unusual as profiles quite commonly are extruded with reduction ratios of 50 and above. In fact, strains may locally be much larger than this value as the deformation during extrusion is extremely inhomogeneous due to extensive shearing. During extrusion aluminum has the characteristics of a viscoplastic fluid, which start to flow when the stress reaches the yield limit, and the extrusion process itself will in principle be a forced unsteady flow through a reduction. Macroscopically, the flow field will be characterized by the local velocities, temperatures and

stresses, for which values can be measured at the boundary between aluminum and container/die.

The velocity field describes the particle velocities at all points in the container and bearing channel and, therefore, also the flow at all times. The rates of strain and rotation of particles may be of larger interest in the study of changes to microstructure during extrusion, but these quantities can be derived directly from the velocity field. However, due to the high pressure and temperature in the container, flow rates are extremely difficult to measure. Conventional flow meters are generally not constructed for the relevant conditions. Furthermore, the velocity field may be expected to be relatively complex and inhomogeneous, especially if complicated profiles are extruded. A few measuring points at the boundary would therefore not reveal all the characteristics of the flow. Only when the material leaves the die, can particle velocities be measured directly and easily. The flow

velocity ought then to be approximately uniform across the profile cross-section, directed normal to the opening and of a magnitude equal to the reduction rate times the velocity of the stem.

As hot aluminum behaves viscoplastically, the material will stop flowing when the extrusion force is relaxed so that stresses fall below yield. This property is important because information about the total deformation of the material will be saved in its structure after extrusion. This is not the case for perfect fluids such as for instance water, for which the measurement of total strains is of both minimal interest and impossible as the material deforms also when forces are removed. In order to establish the deformation history during extrusion, one performs a number of tests which may be interrupted at various stroke lengths. This will provide information on the total deformation at different stages. If the velocity of the stem is known, the approximate flow rate and strain rate at each point may also be calculated. There are a number of variations of this technique, which bears the name viscoplasticity. Model materials such as wax, clay, plasticine or even lead have earlier been used extensively when simulating extrusion of aluminum.^[20] The billets are first parted, and a rectangular grid is applied on the surfaces of each half. The two parts are thereafter extruded together, and the distortion of the grid is in the end studied. The changes in geometry can be used directly to calculate strains and rotations. The use of model material is advantageous in that extrusion can be performed with a low force and that both the equipment and the model material are relatively cheap. There are, however, also a number of short-comings connected to such a use. It is always difficult to be certain that the material models the aluminum correctly, especially since temperature effects, which are totally neglected when using model materials, are known to be of large importance to the flow characteristics of aluminum. Furthermore, model materials are also susceptible to plastic deformation during post-extrusion treatment.

The interest in model materials has over the last years fallen, as modeling of extrusion process has increasingly become the realm of finite element programs. However, the method described above may also be applied to the extrusion of aluminum as shown in Fig. 22. The unmodified version of the technique works well for reduction ratios up to about 3, but at this point the material is so deformed that the grid may be erased locally, especially in shear zones. Valberg^[21-24] has developed an alternative method, which can be applied when extruding at much larger ratios. Some alloys of aluminum share mechanical properties even though their composition may differ. This is the case for a number of AlMgSi and AlCu alloys, the first group remaining gray, the second turning black when etched. Thus, the AlCu alloy may therefore work as a so-called indicator or marker material. By drilling evenly separated longitudinal and transversal holes in different parts of a plane of symmetry and inserting pins of indicator material, a grid is formed (Fig. 23). A certain portion of the billet is then extruded, and the aluminum is carefully removed from the container and die. By splitting the billet and profile along the axis of symmetry, grinding and etching, the deformation of the material is made visible (Fig. 24). A grid pattern may then be reproduced. By this technique metal flow may be investigated up to logarithmic strains of about $\epsilon = 10$.

The marker material technique has been applied in the study of porthole die extrusion,^[25] two-hole die extrusion,^[26] flow adjacent to bearing walls^[27,28] and with a 3D-version^[29] also in the study of more general flow patterns. However, the most easily analyzable results are provided by simple axisymmetric extrusion, which also has been the standard test case for earlier techniques. General theory connected to direct extrusion describes four categories of flow in the container (Fig. 25a). These differ due to varying degrees of friction between metal flow and container walls. Only flow type B is of interest in the study of aluminum extrusion, the reason being that the other types either underestimate the influence

Fig. 22 The split billet technique applied on the extrusion of aluminum. The partial extrusion of a billet at a reduction ratio of about $R = 2$ is shown

Experiments reveal that the flow pattern in the container will actually depend on temperature conditions. If the container is relatively hot, the material in the outer part of the billet will be more mobile due to lower material resistance to flow. As a result the aluminum may no longer stick perfectly to the container wall and in flow of surface material may either take place along the surface of the stem or directly through the shear zone and into the die opening. This is an unwanted effect since the surface material usually contains impurities and defects caused by rough handling of billets or inverse segregation. The flow pattern will also change due to geometrical variations.

of friction or assume inhomogeneous material behavior. After in depth study of flow patterns during both direct and indirect extrusion, Valberg^[30] has proposed two new general flow patterns more in accordance with observations, flow types A₁ and B₁. Figure 25b shows a typical grid on a partially extruded billet at various stroke lengths.

When studying such grids one must bear in mind that the extrusion process is transient in its nature and that the deformation paths will change during extrusion. Whereas the initial deformation may be relatively homogeneous,

Fig. 24 Determination pattern in a partially extruded billet. (a) Reconstructed deformation field; (b) The original patterns on the partially extruded billet

Fig. 25 (a) Classes of flow patterns during axisymmetric extrusion according to Pearson, Dürrschnabel and Valberg; (b) Experimentally determined flow pattern for direct extrusion of aluminum at various stroke lengths

Fig. 26 (a) Original grid on an axisymmetric billet; (b) Deformed grid on an axisymmetric profile (Valberg-plot). The longitudinal axis is scaled

A small reduction ratio will for instance yield a smaller dead zone close to the die, and the result may also then be that material flows directly from the billet surface and out into the die opening.

A study of the deformed grid in the profile after a complete extrusion charge reveals that extruded products are far from homogeneous with respect to the deformation undergone. Figure 26 is a representation of such a grid where

the longitudinal axis is scaled down. The first material leaving the die opening will have undergone a relatively small degree of deformation, but as extrusion proceeds, the material in the profile will have been deformed while passing through at least a part of the primary deformation zone. Region 2 is characterized by a grid that is very homogeneous, indicating that material particles originally coming from the secondary deformation zone have undergone almost the same deformation history. Hence, when extruding this material the process will resemble one of steady state. Region 3, however, is constituted of the material that was hindered from deforming by the stem during the extrusion charge, and the degree of deformation can therefore be expected to be much smaller. A layer of heavily shear deformed material will exist closest to the profile surface.^[32] The growth of this layer towards the end of the profile indicate that the shear zone in the billet gradually will flow out of the container as the stem is brought closer to the die. In order to find how the container is emptied during extrusion, Valberg has developed so-called emptying-diagrams. These consist of lines, on which all particles will need the same amount of time to reach the exit. Hence, the lines are denoted iso-residence-time lines. They are constructed by placing a grid over the extruded profile, finding the crossing points with the deformed grid of the marking material and then tracing these points back to the corresponding undeformed grid in the billet. In Fig. 27c, a number of such lines are shown. As expected, the bulk of the dead zone close to the die will not flow into the die opening until the very end of the charge. During the whole extrusion process, however, parts of the shear zone will be transported out into the profile, and the dead zone will gradually be reduced in size. Figure 27a and b also reveals that the surface layer of

the profile will be generated from the material in the shear zone of the billet.

The observation that the size of the dead zone varies during an extrusion charge is extremely important to the understanding of the extrusion process as a whole. Energetically the process of extrusion through flat dies seem favorable to that through tapered dies, as the metal is allowed to find the most optimal flow path by varying the inclination of the shear zone through the charge. However, as the flow pattern is unsteady, the properties of the product will necessarily also vary along its length. One of the objectives with using feeders such as that shown in Fig. 28, is to stabilize the conditions at the inlet to the bearing channel. In this way deformation paths for particles in the back and in the front of the billet will be more equal. Other reasons for applying feeders, however, are usually viewed as more important. As the metal in the feeder is not removed when the butt of the billet is cut, one may weld metal from two charges together and almost extrude continuously. The advantage of applying a feeder is then that production rates will be increased. The drawback is that the charge weld formed most probably will contain inclusions of oxides and therefore have inferior mechanical and corrosion properties. As charge welds under the influence of varying material velocity over the profile cross section will become a parabolic line extending often many meters along the its length, low weld quality may lead to extensive scrapping.

Temperature and Metallurgy

Variations in temperatures during extrusion seem to influence flow behavior in a number of ways. As indicated, flow patterns may be changed considerably by rendering

Fig. 27 Emptying diagrams for axisymmetric extrusion. (a) and (b) Determination of one iso-residence-time curve; (c) and (d) Complete diagrams for respectively direct and indirect extrusion

Fig. 28 A schematic example of direct extrusion with a feeder

the temperature distribution in the container. Furthermore, it is known that the extrusion pressure may be lowered if either the temperature of the billet or the velocity of the stem is increased, and that there are certain limitations, since the material starts melting or cracking if it leaves the die with a too high temperature. The observations indicate that there is a strong coupling between what would be regarded as thermal and mechanical effects.^[33] In order to describe the temperature field during extrusion, a system for measuring temperature at surface between the flowing alloy and tooling has been developed by Lefstad.^[34,35] The method has its limitations since it does not reveal the complete temperature field, but it is well suited for studying the temperature of the flowing metal on the bearing surfaces close to the outlet. Due to frictional forces the temperature can be expected to be highest in this part of the flow.

In principle, all the effects witnessed on a macroscopic level could be explained with an atomistic perspective. The close coupling between the temperature field and the mechanical forces are simply due to the exchange of kinetic and potential energy of the atoms. Today some phenomena such as frictional behavior and dislocation movement are explained partly with such a perspective,^[36] but no complete atomistic description of the extrusion process can be found in literature. There are presently no ways of performing satisfactory measurements on flow, and the modeling methods are not able to handle the complexity of the problem. Hence, simplifications are sought. As will be explained in the next section, modeling is today primarily performed with the thermo-mechanical continuum theory. This is, however, merely a mathematical tool, which can be used to quantify states of deformation and pressures, and it will not reveal any new fundamental mechanisms. The problems of extrusion, related to speed limits, flow resistance, evolution of microstructure, stability of flow, surface quality and so forth are generally of metallurgical and micro-structural origins. Furthermore, since the flow- and temperature fields are influenced by the flow-resistance of the hot metal, which is strongly dependent on the alloy constituents, microstructure and metallurgical state of the deforming material, there is a strong interaction between flow, temperature and micro-structural evolution. If the continuum theory shall be able to model and quantify such phenomena properly, one must be able to relate the parameters of the model to the thermodynamics and kinetics of the material. An example of such is the description of recrystallization, of whose degree is influenced by such factors as temperature, time

and deformation.^[37,38] When extruded under similar conditions, different alloys need not experience the same amount of recrystallization. If quantitative description of the degree of deformation is to be given by a continuum model, the rate of recrystallization must be related to the values of deformation provided by a mathematical calculation as well as the constitution of the alloy. In the present state of the art of extrusion technology, the continuum description of thin-walled extrusion has not yet reached the point where the metallurgical phenomena can be explained quantitatively based on the continuum-mechanical description of the flow- and temperature field.

An important fact that is often forgotten is that the complete thermo-mechanical history of the material should be known if one is to assess the microstructure. Focus should not only be placed on the mere extrusion charge, but on all the process steps. A study of the influence of Mg_2Si particles on the maximal allowed extrusion speed gives an example of this.^[39,40] The example applies probably to most 6XXX-alloys and in fact also to some of the 7XXX-series. The billet is prepared for extrusion after casting by homogenizing, controlled cooling after homogenizing and preheating before extrusion. Based on the chemical constituents of the alloy (Fig. 29a), given here for an AA6060-alloy (also showing AA6082 for comparison) with equilibrium-diagram (Fig. 29b), the initial temperature distribution in the billet at the starting point of extrusion should be such that the magnesium and silicon are completely in solid solution before the alloy leaves the die. At the same time the extrusion speed should be selected in order to give shortest possible press-cycle time without causing overheating or unacceptable risk for production stops and/or quality problems. If there is eutectic left with melting point at 585°C (Fig. 29d), then this will be the maximum temperature without overheating. Otherwise, the solidus line will give the upper temperature limit. Clearly, by preparing the billet in an optimal manner, high gains in productivity can be achieved.

Studies of microstructure in profiles often reveal a relatively large degree of inhomogeneity over the cross-section. This applies to the size and form of crystals and to the dislocation density. Mechanical testing usually give results in accordance with such observations. As Valberg's experiments explain, this is to be expected because the deformation of the material during extrusion is extremely inhomogeneous, and the same will naturally also be the case for the temperature history. In the early studies of microstructure evolution during extrusion insufficient attention was paid to these facts, and very often only average values of deformation and temperature were assessed. In this way the limits of the extrusion process can hardly be studied and the variability of the process only poorly understood. Figure 29 also explains the importance of knowing the exact temperature-, strain- and strain rate-history for each particle in the deforming alloy and especially for those that undergo the largest strains. The largest differences will be experienced when the material particles enter the

Fig. 29 Relation between metallurgy and process parameters

bearing channel. Here, the material close to the die will be exposed to shear strain rates up to about 10,000 [1/sec], whereas the strain rate in the center of the bearing channel is in the range of 0.1 [1/sec]. As shown on the micrograph Fig. 29e, there is a considerable degree of variation in microstructure in an extruded section. Partial recrystallization over the cross section may here also occur, and this

gives rise to unsatisfactory large variability of properties and surface appearance. Since every material element in the billet goes through different strain rate-, temperature- and strain-histories as shown on Fig. 29d, it is important that the alloy is not very sensitive to these variations with respect to flow resistance and final microstructure after extrusion and quenching and aging (Fig. 29f).

Predicting the Conditions of Flow

Mathematical Approaches

The traditional method of treating macroscopic problems within both solid and fluid mechanics has since the 18th century been through the principles of continuum mechanics.^[41] The fundamental equations obtained within the frames of this perspective are those of motion and conservation of heat, expressed incrementally. Furthermore, the assumption is that processes on a microscopic scale will average out so that the material properties will be continuous functions in space except in the case of discrete discontinuities. Material behavior will, however, be determined by processes taking place at levels from atomic to grain-size. In mechanics, constitutive equations can be utilized to characterize the relationship between measures such as deformation and stress. Purely elastic atomic lattice deformation may be represented by Hooke's law, which is a linear relationship between stress and strain. As elastic behavior generates no permanent deformations and in a thermodynamic sense may be looked upon as ideally reversible, it may also mathematically be characterized by functions of states. From a computational point of view this makes the material model attractive.^[42] Deformations taking place during extrusion, however, contain only a minor and in fact in many cases a negligible elastic component. As the profile is generated from a billet, the material has to undergo permanent deformation. On a microscopic scale this deformation is caused by the sliding of dislocations through the grains.^[43] As long as force is applied, energy will be dissipated, and therefore the process is thermodynamically irreversible. Consequently, the material behavior should be presented mathematically by history dependent functionals.^[44] A further complication is that plastic material behavior usually can be taken to be non-linear. Hence, a theory of plasticity is bound to be of another dimension of complexity compared to purely elastic theory.

Different Perspectives

As extrusion basically is a non-steady flow problem, principles of fluid mechanics may be applied to evaluate both deformation and stresses. The viscosity will in this case be a function of the strain rate. As the material will not flow below a certain yield limit, a constitutive model such as that of Bingham may be appropriate if the necessary corrections are made for temperature effects on yield stress. The fluid mechanical or rheological approach, which addresses strain rates or time increments of strain, is favorable for many reasons.

Firstly, stresses generated through plastic deformation at high temperatures are found to be almost independent of the total strain, but extremely dependent on the strain rate. Secondly, flow is viewed in an Eulerian sense, by which is meant that components of flow velocity and stress

are related to spatial coordinates, and that deformation is assessed in an incremental manner, the reference state at all times being that of the last time step.

Hence, an Eulerian formulation of the constitutive relation will therefore never violate the principle of material objectivity, which states that the constitutive relation should be independent of the choice of reference frame.^[45] A rotation of the element should for instance not cause changes in stresses as long as the strains are held constant. Incremental deformations will to a close approximation always be in accordance with this principle.

Another favorable aspect with an Eulerian description is that computer code can be made very efficient due to the fact that velocities and stresses can be evaluated in a mesh that does not deform. However, as the Eulerian approach only assesses increments, information about each particle's total stress/strain history is lost, and elastic deformation can only with some difficulty be described. When evaluating the flow pattern, elastic strains are generally small, and it can be assumed that they only are of minor influence. However, elastic stresses may be of importance for instance to the surface quality of the product as friction in the bearing channel is affected by pressure due to elastic strains. A last problem connected to the Eulerian description in connection to extrusion is that the extruded profile is free to move as a rigid body in any direction as it leaves the bearing channel. Furthermore, deformation is then not plastic, and the movement will not be confined within certain limits, but should be calculated for the rigid body from the laws of motion. Furthermore, the boundary conditions of traction caused by a puller may not easily be described in the Eulerian system.

The Lagrangian description has traditionally been most popular when describing the movement and deformation of a rigid body. This approach assesses deformation of particles in relation to a fixed reference state in space, thus making use of so-called material coordinates. This view is favorable in that the total strain history is kept, and therefore that both elastic and plastic deformation may be included in calculations. Furthermore, an arbitrary movement of particles in space can be described when boundary conditions are given. This makes it possible to predict deformations also when the material moves out of the bearing channel. A problem is, however, that deformation and rotations tend to be large during extrusion. A Lagrangian description of finite deformation is not automatically in accordance with the principle of objectivity, the cause being that the material derivative of stress is not an objective measure even though stress is. Again this is a minor problem when evaluating only plastic strains as it is done on an incremental basis. However, when adding elastic deformation components the principle of material objectivity is satisfied only by making use of an alternative material derivative of stress that compensates for any rotations of particles. In plasticity theory the Jaumann derivative is in common use. An analytical treatment of finite elasto-plastic deformation

is by no means trivial. Lagrangian numerical calculations, however, are widely performed, and these make use of an element net that moves and deforms with the material particles. Calculation times tend to be higher for Lagrangian codes than for Eulerian even in the case when elastic deformations are disregarded, the reason being that meshes have to be regenerated during simulations due to large distortions and loss of numerical accuracy. A promising method for evaluation of the state of deformation during extrusion seems to be the combination of the two descriptions in an Arbitrary Lagrangian-Eulerian (ALE) code.

Plasticity and Extrusion

Whereas the theory of rheology is focused on solving problems where stresses are given as functions of temperature and strain rates, the classical theory of plasticity was originally established to handle isothermal solid state problems where the stress after having exceeded the yield point, still was a function of strain.^[46–48] An example of such a problem is that of the low-temperature uniaxial tensile test where a plot of true stress to true strain will usually give a monotonically increasing curve. Plastic deformation can be assumed to be initiated when the yield limit is reached. An increase in yield stress as a result of further deformation is called hardening. Several simplified material models have been established so that calculations can be made easier. When applying a perfectly plastic model it is assumed that plastic deformations are dominating and that the material does not strain harden. An elastic/plastic model can be utilized when the elastic strain component is of a certain value (Fig. 30). Strain hardening models such as that of Ramberg and Osgood also simplify matters in that hardening behavior is characterized by one parameter, the hardening exponent.

In principle, one is not to expect that the material shows any strain hardening behavior during extrusion. Such is traditionally connected to the pile up of dislocations, but at characteristic temperatures from 450°C to 600°C recovery and recrystallization mechanisms will contribute to the reduction of dislocation tangles during deformation. At a given stress, continuous deformation should therefore be possible. However, the strain rate will be of importance to

the yield stress as the rates of creation and destruction of dislocation tangles will determine the equilibrium dislocation density. As for temperatures, the yield stress may be expected to follow the same Arrhenius relationship as metallurgical processes generally do. Hence, the yield stress can generally be expressed as a function:

$$\bar{\sigma} = f(\bar{\epsilon}, \dot{\bar{\epsilon}}, T) \quad (7)$$

The equation is given in terms of equivalent stress and plastic strain:

$$\begin{aligned} \bar{\sigma} &= \sqrt{\frac{3}{2}(s_{ij}s_{ij})} \\ &= \sqrt{\frac{3}{2}[(\sigma_x - \sigma_0)^2 + (\sigma_y - \sigma_0)^2 + (\sigma_z - \sigma_0)^2 + 2\tau_{xy} + 2\tau_{yz} + 2\tau_{zx}]} \\ &= \frac{1}{\sqrt{2}} \\ &\quad \sqrt{(\sigma_x - \sigma_y)^2 + (\sigma_y - \sigma_z)^2 + (\sigma_z - \sigma_x)^2 + 6\tau_{xy} + 6\tau_{yz} + 6\tau_{zx}} \quad (8) \end{aligned}$$

$$\dot{\bar{\epsilon}} = \sqrt{\frac{2}{3}(\dot{\epsilon}_{ij}\dot{\epsilon}_{ij})} = \sqrt{\frac{1}{3}(2\dot{\epsilon}_x^2 + 2\dot{\epsilon}_y^2 + 2\dot{\epsilon}_z^2 + \dot{\gamma}_{xy}^2 + \dot{\gamma}_{yz}^2 + \dot{\gamma}_{zx}^2)} \quad (9)$$

The equivalent measures of stress and strain are of interest when the state of stress is multiaxial. It can be shown that dissipation in general can be given as $\dot{w} = \sigma_{ij}\dot{\epsilon}_{ij} = \bar{\sigma}\dot{\bar{\epsilon}}$, and for a purely tensile test the equivalent stresses and strains will reduce to σ_z and ϵ_z . In simulation of extrusion extensive use is made of the Norton-Hoff relation:

$$\bar{\sigma} = K\bar{\epsilon}^n \dot{\bar{\epsilon}}^m e^{\frac{\beta}{T}} \quad (10)$$

where $n = 0$ can be used to remove any strain dependence. n and m are material constants. β is a parameter often set equal to the Q/R where Q is the activation energy and R is the universal gas constant. Another frequently used relation in the study of extrusion is that of Zener and Hollomon^[49] which is given by:

Fig. 30 Simple constitutive relations: (a) Bingham fluid without strain rate hardening; (b) Rigid plastic material without strain hardening; (c) Elastic plastic material without strain rate hardening

$$\bar{\sigma} = \frac{1}{\alpha} \arcsin h \left(\frac{Z}{A} \right) = \frac{1}{\alpha} \arcsin h \left(\frac{\dot{\epsilon} \times e^{\frac{Q}{RT}}}{A} \right) \quad (11)$$

In this case the yield stress is taken to be independent of the total strain. α and A are parameters which can be applied in curve fitting. Experiments indicate that the Zener-Hollomon relation may be satisfactory both when performing torsion tests on aluminum and during extrusion. Improvements to this material law have, however, been suggested. The main difference between torsion testing and extrusion is that the former assumes steady state while the strain rates may vary considerably in the later.

Typical stress-strain curves obtained through torsion, compression or tension tests at temperatures around that of extrusion are shown in Fig. 31. As changes in strain rates and temperatures tend to influence yield stress more than the total strain, rheological modelling seems preferable to modelling through plasticity theory. However, if a perfectly plastic or a plastic material model with low strain hardening is adopted, effects of strain rate and temperature can be implemented by calculating the yield stress on the basis of relations such as Norton-Hoff or Zener-Hollomon. The important point is that a deformation mechanism based on dislocation glide is one of shear and, hence, should be modelled macroscopically as one that relates increments of strains to the deviatoric stress state. Both theories of rheology and plasticity have this perspective and have for a long time been widely used to describe the extrusion process. Early analytical and semi-analytical work has, however, not managed to solve the complex problem of extrusion in its entirety. Rheological approaches have been based on simple material models and have only assessed very simplified flow fields. Techniques related to plasticity theory have traditionally been popular when calculating very rough estimates of for instance the necessary extrusion force. By applying the so-called slip line theory one has been able to find closed form solutions for particle paths and stress states for simple geometries, but material models are generally limited to perfectly plastic, and temperature effects and material anisotropy have been neglected. However, modern numerical programs offer the user the possibility to implement constitutive models based on microstructural

Fig. 31 More general stress-strain curves' dependence on temperature and strain rates

considerations and are able to perform coupled thermomechanical analysis for complex geometries. The last being of greatest importance due to the large variation in temperature in the container and bearing channel. Furthermore, by obtaining the temperature and strain history of the individual particles numerical programs should be able to describe changes in microstructure and the consequences of these. Both continuum plasticity theory and rheology are the building bricks for such programs.

Yield Criteria

For tensile tests yielding is initiated when the axial stress component reaches the yield limit, $F(\sigma_z) = 0$. In the general case it can be expected that all components of stress have an influence on the point of yielding, and in a six-dimensional space a yield surface $F(\sigma_{ij}) = 0$ may be defined. The assumption is made that deformation is purely elastic in the case where $F(\sigma_{ij}) < 0$. In classical plasticity theory one then usually resorts to two simplifications. The first is that the material is isotropic, thus implying that the yield surface is determined only by the principle stresses, $F(\sigma_1, \sigma_2, \sigma_3) = 0$, and therefore also the stress invariants, $F(J_1, J_2, J_3) = 0$. The second is that the hydrostatic pressure has no effect on yielding. Then the yield criterion can be written in terms of the deviatoric invariants:

$$F(J'_2, J'_3) = 0 \quad (12)$$

where

$$J'_1 = S_{ij} = 0 \quad J'_2 = \frac{1}{2} S_{ij} S_{ij} \quad J'_3 = \det(S_{ij})$$

and S_{ij} is the deviatoric stress, $S_{ij} = \sigma_{ij} - \sigma_0 \delta_{ij}$. σ_0 is the hydrostatic stress. The assumptions made are more or less applicable to most engineering materials. However, alternative anisotropic yield criteria have been developed so that materials with strong anisotropy can be handled.

When applying the assumptions of isotropy graphical representation of the yield criterion can be made in the 3 dimensional $\sigma_1, \sigma_2, \sigma_3$ -space. By assuming that hydrostatic pressures do not influence yielding, one is able to reduce the yield surface to a yield locus in the deviatoric plane, which is defined by the normal $(\sigma_1, \sigma_2, \sigma_3) = (1, 1, 1)$. If it is assumed that the material is isotropic and that yielding will take place at the same stress level both in tension and compression, the yield locus must be symmetric about the six axes defined by the projections of the σ_1, σ_2 and σ_3 -axes into the deviatoric plane. The last assumption is, however, not always correct due to the Bauschinger effect, which will be explained later.

The most commonly applied yield criteria are those of von Mises and Tresca. The von Mises criterion assumes that F only is a function of the second invariant of deviatoric stress. For many materials, experiments often indicate

that yielding only to a very limited extent is dependent on the third invariant and thus confirms the hypothesis of von Mises. Mathematically the representation is:

$$J_2' - K_M^2 = \frac{1}{6}[(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2] - k_M^2 = 0 \quad (13)$$

Hence, the von Mises criterion has the nice property that it appears as a circle in the deviatoric plane. Furthermore, the second invariant of deviatoric stress is simply the square of the expression for equivalent stress. This indicates that the von Mises criterion bases the criterion of yielding on the deformation energy absorbed by the material. The natural alternative to this is the Tresca criterion, which states that yielding will take place when the maximum shear stress reaches a critical value. This may be expressed as:

$$\tau_{\max} = \max \left[\frac{1}{2} |\sigma_1 - \sigma_2|, \frac{1}{2} |\sigma_2 - \sigma_3|, \frac{1}{2} |\sigma_3 - \sigma_1| \right] = k_T \quad (14)$$

The yield locus will in this case be a hexagon in the deviatoric plane. Also the Tresca criterion may be expressed in terms of the second and third invariants. In Fig. 32 both the von Mises and the Tresca yield loci are presented. Which one of the criteria that are the most conservative depends on the choice of k_M and k_T . If it is assumed that yielding first is taking place at a characteristic yield stress for pure tension, σ_Y , one would expect that:

$$k_M = \frac{\sigma_Y}{\sqrt{3}} \quad k_T = \frac{\sigma_Y}{2} \quad (15)$$

The result is that the locus of the von Mises criterion will circumscribe that of Tresca. However, if the shear stress is the reference for yielding then both are given as $k_M = k_T = \tau_Y$. In this case the Tresca criterion is the least conservative except in the point of maximal shear.

An interesting property of the yield locus is that singular points may exist, such as the case for the Tresca criterion. The singularity should from a macroscopic perspective be explained as a result of the sudden change of plane of maximum shear stress when loading from one state of stress to another. Consequently, the plane of shear deformation is also changed. However, the Tresca yield locus can also be explained on the basis of knowledge about glide systems in fcc-crystals. As a simplification, a state of plane stress is assumed. In this case shear deformation through dislocation movement may take place in three separate groups of planes (Fig. 33). The principal stresses are directed along the axes of the coordinate system. The same axes also define the (1 0 0) [1 0 0] texture of the fcc-lattice, which is taken to be homogeneous, so that all the grains have oriented the {1 0 0} plane normal to the x -direction. If it is assumed that deformation is only taking place on the glide plane with the largest shear stress, the ratios of the stresses $\sigma_x : \sigma_y : \sigma_z$ will determine the deformation of the grains. If σ_x is the largest stress and $\sigma_z = 0$ the smallest, one can expect that the first glide system will be operative. Subsequently, if σ_y is the largest stress and $\sigma_z = 0$ the smallest, deformation will be of the second type. The last alternative is that σ_x and σ_y are the extreme principal stresses in which case the third modulus of deformation is relevant. With the help of Schmid's law a yield locus can be constructed in the $\sigma_x \sigma_y$ -plane. Figure 33 shows that such an analysis renders the Tresca yield locus. The singular points are the results of a limited amount of glide systems. While single crystal materials might follow a yield criterion such as that of Tresca, most materials contain grains with all sorts of orientations and glide systems. In this case deformation will take place in a series of directions yielding a number of straight lines defining a yield locus that resembles that of von Mises. A locus without singularities is often denoted regular.

Strain Hardening and Plastic Flow

Material behavior at stresses above the yield limit will depend on both the hardening behavior and boundary

Fig. 32 The yield surface, the yield locus and the deviatoric plane

Fig. 33 (a) An ideal (1 0 0)[1 0 0] texture; (b) The yield locus for ideal (1 0 0)[1 0 0] texture material

conditions. Whereas flow of a perfectly plastic material will be completely restricted by outer constraints, deformation of a strain hardening material can only take place if the stresses are increased gradually. Furthermore, in order to calculate deformations a constitutive relation between stresses and strains has to be established. An interesting observation in relation to the preceding determination of the yield locus on the basis of microplasticity, is that any increment of plastic strain will be in a direction normal to the yield surface. Thus, an indication is given that both stresses and strains can be determined if the form of the yield surface is known during deformation.

A uniaxial tensile test can be performed to determine the increase of yield strength during plastic deformation. However, as such a test alone is not able to describe the form of the yield surface during triaxial loading, firm knowledge of changes caused by yielding are even harder to obtain. The most attractive hardening principle mathematically is the isotropic (Fig. 34a). When applying this principle it is assumed that plastic deformation causes the yield surface to expand uniformly. Hence, upon yielding the expression:

$$F(J'_2, J'_3, \bar{\sigma}) = f(J'_2, J'_3) - \bar{\sigma} = 0 \quad (16)$$

Applies. The equivalent stress is taken to be a function either of the energy spent during plastic deformation or the total plastic strain. These are denoted the work hardening and the strain hardening hypothesis respectively. Such functions can be obtained through tensile and compressive testing. The main problem with an assumption of isotropic hardening is that it is not in accordance with the Bauschinger effect, which can be witnessed during cyclic loading. After the material has been deformed plastically in tension, yielding will take place at lower compressive stresses than that of the expected yield point in compression. Kinematic hardening rules describe a movement of the yield surface in space so that the ratio of the yield limits in different directions is altered. A mathematical expression that can be used to describe such a behavior is:

$$F(S_{ij}, \alpha_{ij}) = f(S_{ij}, \alpha_{ij}) - k = 0 \quad (17)$$

where α_{ij} describes the movement of the yield surface and is known as the back ratio. κ will for a strict kinematic rule be a constant. However, newer models often let both α_{ij} and κ vary so that the proposed law can be better fitted to data.

Fig. 34 Strain hardening rules: (a) Isotropic; (b) Kinematical

In the mathematical treatment of plastic strains generated by loading it is rational to define a plastic potential, g , which is to set the ratios of the plastic strain increments. One can expect that this function, as the yield function, originally is one of all stress components. If such a relation is known, the plastic stresses can be derived from the mere definition of a potential function, namely that the increment of strain shall be normal to the potential surface:

$$d\varepsilon_{ij}^p = \frac{\partial g}{\partial \sigma_{ij}} d\lambda \quad (18)$$

$d\lambda$ is simply a constant. The previous microplastic considerations have shown that the yield surface at least in the case of yield by the Tresca criterion also can be expected to be a potential surface. If g is set equal to f , the associated flow rule is adopted. Such an assumption can in most cases be expected to yield satisfactory results because many of the characteristics of g are equal to those of f . Whereas the assumption that yielding is unaffected by hydrostatic stress limits the evaluation of yield to the deviatoric plane, a choice of an incompressible material model leads to the conclusion that the hydrostatic stress line in a $\sigma_1\sigma_2\sigma_3$ -system nowhere can be perpendicular to a potential surface. Hence, a potential surface will be fully described by its locus in the deviatoric plane. As plastic deformation is one of shear, an assumption about incompressibility leads only to marginal errors. Mathematically such a relation is written:

$$d\varepsilon_x^p + d\varepsilon_y^p + d\varepsilon_z^p = \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix} \begin{bmatrix} d\varepsilon_1^p & d\varepsilon_2^p & d\varepsilon_3^p \end{bmatrix} = 0 \quad (19)$$

In the $\sigma_1\sigma_2\sigma_3$ -system an incremental change in strain will generate the stress component $2G(d\varepsilon_1^p, d\varepsilon_2^p, d\varepsilon_3^p)$, where G is a constant of proportionality. It can be observed that this component has a direction perpendicular to the line $(\sigma_1, \sigma_2, \sigma_3) = (1, 1, 1)$ and therefore lies in the deviatoric plane. The locus described in such a

Fig. 35 The yield locus in relation to Drucker's hardening postulates

plane by a potential surface, also has to be symmetrical with respect to the stress axes due to assumptions of isotropy and independence of sign reversals. When one discusses states of stresses and the corresponding increment of strains, the incompressibility assumption allows one to view these states as vectors in the deviatoric plane (Fig. 35).

Drucker has proved that unless the material shows strain softening behavior such as that of for instance soils and rocks, the flow rule will be associated and the normality rule will hold. Drucker then has defined a stable material as one for which the inequality:

$$W = \int_{C\sigma} \Delta \sigma_{ij} d\varepsilon_{ij} = \int_{C\sigma} (\sigma_{ij} - \sigma_{ij}^o) d\varepsilon_{ij} \geq 0 \quad (20)$$

holds during a complete load cycle where the original stress state, σ^o , may or may not be one of yielding. A material on which an external agency does positive work during an elastic-plastic stress cycle is considered strain hardening. As the inequality will not be satisfied if the material is strain softening, the postulate is often referred to as Drucker's strain hardening postulate. To a close approximation the net plastic work done over the loading part of the cycle can be expressed as:

$$(\sigma_{ij} - \sigma_{ij}^o) d\varepsilon_{ij}^p + \frac{1}{2} d\sigma_{ij} d\varepsilon_{ij}^p > 0 \quad (21)$$

Drucker's first and second postulate follows from this inequality. If it is assumed that the original state of stress is one of yielding, the first term cancels. In accordance with the inequality, the first postulate states that the plastic work done by an external agency during the application of additional stress is positive for a work hardening and zero for a non-hardening material. If the last part of the postulate is to be true, vectors representing the increments of stress and plastic strain have to be perpendicular. In a non-hardening material loading is assumed to be neutral, that is all load paths are tangential to the yield surface. Therefore the increment of strain is directed normally to it, thus resulting in the normality law. If the material is hardening, it must be assumed that the increment of stress is a linear combination of a plastic and an elastic part, and that the last is directed tangentially to the yield surface. As the elastic part of the stress increment does no irreversible work, the increment of plastic strain is also in this case directed normal to the yield surface.

Drucker's second postulate is connected to the first part of the inequality above and states that the net work done by an external agency during a cycle of addition and removal of stresses is non-negative. If it is assumed that the original state of stress is not one of yielding, the last term in the inequality can be neglected. The result is:

$$(\sigma_{ij} - \sigma_{ij}^o) d\epsilon_{ij}^p > 0 \quad (22)$$

This inequality also bears the name the maximum work theorem. From Drucker's second postulate it can be seen that the angle between the vectors $\sigma - \sigma^o$ and ϵ^p is always normal to the yield surface and σ^o is located inside the yield surface, this surface has to be convex at all points.

If it is assumed that yielding is initiated according to the von Mises criterion and that the flow rule is associative, the plastic strains can be calculated to be:

$$d\epsilon_{ij}^p = \frac{\partial f}{\partial \sigma_{ij}} d\lambda = \frac{3}{2\sigma} (\sigma_{ij} - \sigma_{ij}^o \delta_{ij}) d\lambda = \frac{3S_{ij}}{2\sigma} d\lambda \quad (23)$$

This rule can also be written in the form:

$$\frac{d\epsilon_x^p}{S_x} = \frac{d\epsilon_y^p}{S_y} = \frac{d\epsilon_z^p}{S_z} = \frac{d\gamma_{xy}^p}{\tau_{xy}} = \frac{d\gamma_{yz}^p}{\tau_{yz}} = \frac{d\gamma_{xz}^p}{\tau_{xz}} = d\lambda \quad (24)$$

indicating that the increments of strain are proportional to the deviatoric stress components. If the material is assumed to be rigid/plastic, the names of Lévy and von Mises are connected to the equations. If the material model also contains an elastic strain component the above relations are those of Prandtl and Reuss.

The constant of proportionality $d\lambda$ is expected to be related to the increment of equivalent strain, the reason being that the increment of plastic strain is determined by the strain hardening behavior of the material. By applying the measures of equivalent stress and strain one can relate the hardening behavior of a uniaxial test to that of the multiaxial actual load case. From the definition of equivalent stress and strain it is known that:

$$\dot{\bar{\epsilon}} = \dot{\bar{\sigma}} = \sigma_{ij} \dot{\epsilon}_{ij} = S_{ij} \dot{\epsilon}_{ij} \quad (25)$$

If only plastic components of strain are evaluated, the flow rule can be applied in order to eliminate the increment or in this case the material derivative of plastic strain:

$$\dot{\bar{\epsilon}} = S_{ij} \left(\frac{3}{2\bar{\sigma}} S_{ij} \right) \dot{\lambda} = \bar{\sigma} \frac{\dot{\lambda}}{\bar{\sigma}} = \bar{\sigma} \dot{\lambda} \quad (26)$$

This gives the result $\dot{\lambda} = \frac{\dot{\bar{\epsilon}}}{\bar{\sigma}}$ or $d\lambda = \frac{d\bar{\epsilon}}{\bar{\sigma}}$ and a final flow rule of the form:

$$d\epsilon_{ij}^p = \frac{3d\bar{\epsilon}^p}{2\bar{\sigma}} (\sigma_{ij} - \sigma_{ij}^o \delta_{ij}) = \frac{3d\bar{\epsilon}^p}{2\bar{\sigma}} S_{ij} \quad (27)$$

The total strain increment will generally be the sum of both an elastic and a plastic part. The elastic component can be obtained by the use of Hooke's law on an incremental

form, and from this equation it can be seen that the ratio of the components of elastic strain will be determined by the increment of stress and not the full deviatoric stress as the case is for the plastic component. A particular formulation of stress-strain relationship developed by Hencky assumes that also the ratios of plastic strains are given by those of deviatoric stress. This can only be expected to hold if the loading is proportional, that is, if the stress components experience a proportional increase during loading. As initially indicated the load path is generally history dependent and must be calculated incrementally.

The Uniqueness Theorem

The Lévy-Mises equations reveal both the strengths and the weaknesses connected to the description of extrusion through the theory of plasticity. Deformation is described as one that is initiated by deviatoric stresses and the components of deformation will be determined by their ratio. This is in accordance with the notion that plastic deformation is connected to the glide of dislocations. However, the material is expected to experience strain hardening defined by a curve relating the equivalent stress and strain. At the relevant temperatures little hardening is experienced and, therefore, the derivative of a stress-strain curve will be almost zero. This means that it is not possible to calculate the total strain from the stress alone. Thus, the stress state in the material during extrusion will not be determined by the strain, but by geometry of the tooling and by temperatures and strain rates.

An important property that applies to hardening and non-hardening materials alike is that the state of stress is unique when certain tractions, T_j , and velocities, v_j , are defined on separate parts, S_F and S_v , of the boundary. The proof of this is as follows for a non-hardening material strains. One may assume that two consistent solutions, (σ, v) and (σ^o, v^o) , for the stress and associated velocity distribution, that corresponds to the same boundary conditions, exist. The principle of virtual work is then applied to the differences in the field quantities over the volume of interest:

$$\int (T_j - T_j^o)(v_j - v_j^o) dS = \int (\sigma_{ij} - \sigma_{ij}^o)(\dot{\epsilon}_{ij} - \dot{\epsilon}_{ij}^o) dV + \int (k - \tau^o)[v] dS_D + \int (k - \tau)[v^o] dS_D^o \quad (28)$$

The two last terms are connected to the virtual energy dissipated due to velocity discontinuities $[v]$ and $[v^o]$ on surfaces S and S^o in the volumes with the solutions (σ, v) and (σ^o, v^o) respectively. k is the shear stress on the surfaces of discontinuity, and it is known that neither τ nor τ^o may be larger than k . Hence, the two last integrals on the right hand side will yield solutions greater or equal to zero. The integral on the left side must be equal to zero since it is

assumed that the same boundary conditions are applied in the two cases. The maximum work inequality gives:

$$(\sigma_{ij} - \sigma_{ij}^o)(\dot{\epsilon}_{ij} - \dot{\epsilon}_{ij}^o) = (\sigma_{ij} - \sigma_{ij}^o)\dot{\epsilon}_{ij} + (\sigma_{ij}^o - \sigma_{ij})\dot{\epsilon}_{ij}^o \geq 0 \quad (29)$$

It follows that both terms on the right hand side are positive and that they must separately vanish. This can only take place if $\sigma = \sigma^o$. The two states of stress are equal. In the case of extrusion the value of the yield strength will not be a constant but a function of temperature and strain rate and therefore of spatial coordinates. The above analysis, however, seems to apply also in this case because the volume of material can always be made so small that spatial variations can be overlooked.

In relation to extrusion the uniqueness theorem states that if the load on the tools can be determined uniquely one may in theory also expect to find a unique stress distribution in the flowing metal. However, the matters are complicated by the fact that in reality boundary conditions on the tools are not prescribed but determined by a friction rule. Tresca friction and assumption of full sticking will not cause any problems as it is characterized by a tangential shear stress with a value of yield, but some simplifications have to be made so that the uniqueness theorem may hold also for Coloumb friction.

The determination of the unique state of stress constitutes no small problem even though such a state is known to exist. In the early parts of the development of the theory of plasticity the extrusion process represented a natural test case for analytical work. Therefore, several solutions based on larger and smaller simplifications have been developed. Usually one assumes the material model to be perfectly plastic, and the yield stress to be independent of both strain rate and temperature. The geometry is taken to be either plane or axially symmetric. A state of plane strain corresponds to the extrusion of an infinitely thick plate while axial symmetry only yields cylinders.

Upper and Lower Bound Solutions

The plasticity theory has the advantage that it facilitates a simple procedure for calculation of an upper and a lower estimate for the boundary forces needed to cause plastic deformation. Such estimates can be obtained for a range of material models and in the presence of both small and large deformation. If it is assumed that the yield behavior is perfectly plastic the simplest estimates can be reached. In order to obtain a lower bound on applied forces one assumes a stress field, σ^o that satisfies the equilibrium equations and boundary conditions without violating the yield condition. As the stresses need not be in accordance with a constitutive relation, such a field will generally not be the actual and is instead denoted statically admissible. The actual stress and associated strain is σ and ϵ . The principle of virtual work can in this case be written as:

$$\int (T_j - T_j^o) v_j dS = \int (\sigma_{ij} - \sigma_{ij}^o) \dot{\epsilon}_{ij} dV + \int (k - \tau^o) dS_D \quad (30)$$

where S_D are the surfaces of velocity discontinuity for the actual solution, and κ is the shear yield stress. $[\nu]$ is the actual velocity discontinuity. As the admissible shear stress on the actual discontinuity, τ^o , will not be larger than κ , the last integral on the right hand side is not negative. The first integral is non-negative by the maximum work inequality. In this case the traction caused by the actual stresses and statically admissible ones need not be the same. If the velocity normal to the boundaries where forces are prescribed, S_p , are assumed to be zero, the following will hold on the rest of the boundary, S_v :

$$\int T_j v_j dS_v \geq \int T_j^o v_j dS_v = \int l_i \sigma_{ij}^o v_j dS_v \quad (31)$$

The lower bound theorem, thus, states that the rate of work done by actual surface tractions on S_v is greater than or equal to that done by surface tractions in a statically admissible stress field. If the v_j is uniform on S_v , one will find that the load of the statically admissible field will give a lower bound to the actual one. The principle can be directly applied in extrusion. The velocities normal to the container wall and the die will be zero. S_v can be assumed to consist of two parts, the surface between the billet and the stem and surface defined by the die opening. The tractions on the last part of the surface can be assumed to be approximately zero. Hence, as the velocity on the surface of the stem is uniform, an analysis will yield a lower estimate of the extrusion force at a certain time during extrusion.

Figure 36a gives an example of a statically admissible flow field. The extrusion is assumed to be frictionless. Lines of stress discontinuity are drawn. The normal stress components to such lines as well as the shear stress have to be continuous if equilibrium is to be achieved. The normal component of stress along the line, however, may differ from one side of the discontinuity to the other as shown in Fig. 37. In Fig. 36b the Mohr circles for all the stress states are drawn. Two interesting observations can be made. Firstly, the yield criterion will nowhere be violated, and secondly, a stress discontinuity only amounts to a rotation of the Mohr circle about a vertical line going through the point (σ, τ) . Geometrical considerations limit the use of the proposed field to cases where the reduction ratio is equal to or larger than three. The necessary pressure applied to the billet in order to cause yielding has been calculated to be $p = 5k(R - 1)/R$, where k is the shear yield stress.

In order to obtain an upper estimate on the extrusion force the upper bound theorem is applied. One can assume that v^o is a continuous velocity field satisfying the incompressibility condition. Then the material derivative of ϵ^o may be calculated and the corresponding stress σ^o is

Fig. 36 (a) Statistically admissible stress field during extrusion; (b) The corresponding states of stress in a Mohr diagram

Fig. 37 Possible stress discontinuity in the deforming material

finally obtained from the normality rule. The actual strain rate is denoted $\dot{\sigma}$. The virtual work principle can be used to obtain the following relation:

$$\int T_j v_j^o dS = \int \sigma_{ij} \dot{\epsilon}_{ij}^o dV + \int \tau [v^o] dS_D \quad (32).$$

The assumed velocity field may contain surfaces of discontinuity $[v^o]$. It is known that the actual shear stress, τ , on the virtual surface of discontinuity can not be larger than k . By the maximum work inequality, $\sigma_{ij} \dot{\epsilon}_{ij}^o \leq \sigma_{ij}^o \dot{\epsilon}_{ij}^o$ as σ^o is on the yield surface while σ may either be inside or on. If the virtual velocity field, v^o , is regarded to be kinematically admissible, it also satisfies the boundary conditions on the part of the surface where the velocity is prescribed, S_v . The last equation is then rendered, resulting in the inequality:

$$\begin{aligned} \int T_j v_j^o dS_v &\leq \int \sigma_{ij}^o \dot{\epsilon}_{ij}^o dV + \int k [v^o] dS_D - \\ \int T_j v_j^o dS_F &= \int T_j^o v_j^o dS_v \end{aligned} \quad (33)$$

The upper boundary theorem, thus, states that the rate of work done by the unknown surface tractions on S_v is less than or equal to the rate of internal energy dissipated in any kinematically admissible velocity field. The last equation to the right of the inequality sign may be used to obtain an expression for an upper limit on the extrusion force applied. This limit is denoted T_j^o .

In Fig. 38a a kinematically admissible flow field for axisymmetric extrusion analog to that proposed by Avitzur^[50–52] is shown. The material is assumed to flow like rigid body with speed of the stem, v_o , in the leftmost

Fig. 38 Kinematically admissible flow field similar to that proposed by Avitzur

part of the container. At the surface where the material enters the deformation zone there is a discontinuity in velocity of $v = v_o \cos \theta$ tangential to surface marking the inlet to the primary deformation zone (Fig. 38b). Then the material velocity increases according to the relation $v = v_o \left(\frac{r_o}{r} \right)^2 \cos \theta$. In the end of the zone a new discontinuity is encountered. In the dead zone surrounding the deformation zone the material is assumed to be rigid. The velocity field described is kinematically admissible, but it need not be the actual field. The experiments performed by Valberg and presented earlier, show that the dead zone will communicate with the flow and that no absolute velocity discontinuity will exist between the flow and the dead zone. Instead the flow velocity is expected to gradually decrease towards the container wall. At all times a boundary layer will exist along the whole container wall and one can not expect the leftmost zone to be perfectly rigid. Furthermore, the form of the velocity field will change as the stem is brought closer to the die. In the limiting case, the material will flow in a radial direction towards the bearing channel and the whole dead zone will disappear. As extrusion proves to be a transient process, the solution obtained will only be applicable at a certain stage. However, as long as all the relevant effects are taken into consideration, the proposed velocity field will produce an upper bound on the force needed to initiate deformation. Better upper bounds may be found in literature,^[53–56] but for these calculations may be more complicated.

According to the last equation and Fig. 38a the work that the stem does on the metal has to compensate for the dissipation of energy in the deformation zone, on the surfaces of velocity discontinuity and in connection with shearing of material on the discontinuity close to the dead zone. In addition, the extrusion force has to be increased due to friction in the container and on the yield surface. Fortunately, in an upper boundary analysis each effect can be treated separately. The force needed to deform the material in the two velocity discontinuities can be shown to be equal. The change in velocity over the first discontinuity is according to Fig. 38b $[v] = v_o \sin \theta$. Integration has then to be performed over the whole surface of discontinuity, which is assumed to spherical:

$$F_D \cdot v_o = 2 \int_A k[v] dA = \int_0^\alpha k v_o \sin \theta \times 2\pi R^2 \sin \theta d\theta$$

$$= 2k \times \pi r_o^2 \left(\frac{\alpha}{\sin^2 \alpha} - \cot \alpha \right) \times v_o \quad (34)$$

As v_o appears on both sides and can be dropped, an expression for the force FD is obtained.

An expression for the force F_F caused by the friction between the dead zone and the flowing material can be

obtained if the third term on the right side of the upper bound inequality is integrated over a conical surface:

$$F_F v_o = \int_{A_2} \tau_j v_j dA = k \int_{A_2} v_o \left(\frac{r_o}{r} \right)^2 \cos \alpha dA$$

$$= k v_o r_o^2 \cos \alpha \int_{\frac{q}{\sin \alpha}}^{\frac{r_o}{\sin \alpha}} \frac{1}{r^2} 2\pi r \sin \alpha dr$$

$$= \pi r_o^2 \sin \alpha \cos \alpha \ln \left(\frac{r_o}{r_1} \right)^2 \times v_o \quad (35)$$

Again an expression for the force is obtained by dropping the term v_o , which appears on both sides of the equality.

The force needed to deform the material in the primary deformation zone can be estimated by using the first term on the right hand side of the upper bound inequality. Given the velocity field v , the components of strain may be expressed as:

$$\dot{\epsilon}_r = -2\dot{\epsilon}_\theta = -2\dot{\epsilon}_\phi = -2v_o \frac{r_o^2}{r^3} \cos \theta$$

$$\dot{\epsilon}_{r\theta} = -\frac{1}{2} v_o \frac{r_o^2}{r^3} \sin \theta \quad \dot{\epsilon}_{r\phi} = \dot{\epsilon}_{\theta\phi} = 0 \quad (36)$$

The equivalent strain rate is expressed in the same way in the $r\theta\phi$ -coordinate system as in one of xyz, and as a result the equivalent strain will be given as $\left(\frac{v_o}{\frac{1}{3^2}} \right) \left(\frac{r_o^2}{r^3} \right) (11 \cos^2 \theta - 1)$. A calculation of the given conical volume integral then results in the following expression:

$$F_v v_o = \int_v \bar{\sigma} \dot{\epsilon} dV = \bar{\sigma} \int_{r_1}^{r_o} \int_0^\alpha \dot{\epsilon} \times \pi r \times r d\theta dr = \frac{\bar{\sigma}}{\sqrt{3}} \pi r_o^2$$

$$\int_0^\alpha \sin \theta \sqrt{11 \cos^2 \theta + 1} d\theta \ln \left(\frac{r_o}{r_1} \right)^2 v_o \quad (37)$$

As expected all components of force are dependent on the yield stress given in terms of shear or equivalent stress. Furthermore, the angle α , which defines the dead zone, also has an influence on the extrusion force. Most importantly, however, the expressions indicate that the force is a function of the reduction ratio. If all terms are added and the reduction ratio, R , is the only parameter of interest the force equation may be written:

$$F = a + b \ln R \quad (38)$$

Experiments confirm this relationship for various metals over a range of extrusion speeds. The equation may also be expected to hold for various profile geometries, but more complex profiles will generally necessitate a higher extrusion force than simpler ones with the same R -ratio since the friction surface to total volume ratio can be expected to be larger.^[57,58] Therefore, the constants a and b will be dependent on profile geometry. The value of a and F will also vary over the press cycle as shown in Fig. 39. In the case of direct extrusion the largest variations are due to the fact that both the surface area and friction force between billet and container decrease over time. However, other variations may be expected as the movement of the stem alters the geometry of the flow field. In the last phase of the extrusion charge, the press force will experience a sharp increase as the material from the dead zone moves towards the bearing channel. Another reason for variations in press force is an increase or a decrease in yield stress caused by variations in strain rates or temperatures. The degree of hardening will be highest in the last part of the charge as the metal then experiences very high strain rates. A high degree of plastic deformation causes dissipation of energy and potentially also temperature variations in time and space. If the billet is not properly preheated, temperatures particularly in the central deformation zone, close to the container wall and in the bearing channel will increase gradually, resulting in lower flow resistance.

Slip Line Theory

As shown, the calculation of an upper and a lower boundary estimate may be carried out relatively effortlessly, but such estimates only yield a certain indication of one parameter of interest, the extrusion force. Whereas the lower boundary estimate reveals nothing in connection to the velocity field, the upper boundary calculation gives no indication of the stresses present in the flowing metal. Furthermore, the proposed velocity and stress fields are only kinematically and statically admissible respectively, and will only in the limiting case be equal to the actual fields. An exact solution has only for a few problems been indicated by the

equivalence of the upper and lower bounds. Generally, a principle of maximizing or minimizing of energy can not be expected to yield the exact solution since the proposed form of the field can not be expected to be correct in the very beginning. Therefore, the most interesting parameters to the quality of the finished products such as temperature, strain and strain rate history of individual material elements can not be obtained through the presented limit analysis.

The theory of slip line fields assumes that either a state of plane strain or axial symmetry exists. Furthermore, when elastic strains are neglected, calculations may be made for hardening as well as non-hardening materials. An assumption of a constant yield stress, however, leads to the simplest results. The method will at least provide an estimate of both the stress and velocity field. The slip line method is also one that is based on an initial proposal of a kinematically admissible velocity field. However, by combining the kinematical evaluation with the use of equilibrium equations, constitutive relations and stress boundary conditions, the proposed field will yield stresses that are in equilibrium and actually also satisfy boundary conditions. However, one is not guaranteed that the stresses in the assumed rigid region do not violate the yield condition and that they are in equilibrium. Therefore, a proposed slip line field may be viewed as an upper bound, which in the limit will be an exact solution. But, as this solution is obtained in a more rigorous manner through a relatively systematic procedure of the slip line theory than through a standard upper bound analysis, a firmer knowledge of the strain and strain rate history for a particle can be gained. Furthermore, by obtaining knowledge of the flow line of the material, one will also be able to calculate adiabatic changes in temperature.

If it is assumed that the material responds perfectly plastic to loading, the constitutive relation will be that of Levy and von Mises. Plane strain is assumed and the z -direction is taken to be perpendicular to the plane. Since the material is incompressible, the coordinate strain increments, $d\epsilon_x$ and $d\epsilon_y$ will be equal in magnitude but opposite in sign. Hence, the deformation will be one of pure shear. As $d\epsilon_z$ is set to

Fig. 39 General relation between extrusion force and stroke length

zero, the Lévy-Mises equation for the z -direction can be applied in order to obtain:

$$\sigma_z = \frac{1}{2}(\sigma_x + \sigma_y) \quad (39)$$

Equation 39 shows that the largest and smallest stresses at all times may be found in the xy -plane, which is in accordance with the fact that deformation is one of shear in this plane. Furthermore, the stress σ_z is equal to the hydrostatic stress. Since extrusion is a process in which the hydrostatic stress may assumed to be negative, the negative sign convention is applied, $p = -\sigma_z$. If it is assumed that the material follows the von Mises criterion for yielding, the last equation can be applied in 13. The result is:

$$(\sigma_x - \sigma_y)^2 + 4\tau_{xy}^2 = 4k^2 \quad (40)$$

where k is the shear yield stress. It can be observed that if relations for the normal stress, σ , and the shear stress, τ , on a surface with an inclination of ϕ to the x -axis is calculated, squared and added the Mohr circle emerges as:

$$\left(\sigma - \frac{1}{2}(\sigma_x + \sigma_y) \right)^2 + \tau^2 = \frac{1}{4}(\sigma_x - \sigma_y)^2 + \tau_{xy}^2 \quad (41)$$

Hence, in a Mohr-diagram all stress states in the plastic region will be described as circles with radiuses of magnitude k . From the typical Mohr-circle in Fig. 40b it can be seen that the state of stress at each point in the material can be described merely by the hydrostatic pressure, p , and the orientation, ϕ , of the plane with the largest shear stress:

$$\begin{aligned} \sigma_x &= -p - k \sin 2\phi & \sigma_y &= -p + k \sin 2\phi \\ \tau_{xy} &= k \cos 2\phi \end{aligned} \quad (42)$$

A new coordinate system $\alpha\beta$ can then be defined so that the shear stress has its maximum value along the axes α and β . A convention is then that the line of action of the algebraically greatest principal stress makes a counter-clockwise angle of $\frac{\pi}{4}$ with the α -direction (Fig. 40). As the plane of greatest shear changes from point to point in the material, the coordinate system will have to be curved. However, the α - and β -lines will still be orthogonal at each point. Since the deformation is expected to be one of shear, the α - and β -lines are called slip lines or shearlines.

As the deformation is assumed to be quasi-static and body forces are neglected, the equations of equilibrium reduce to:

$$\frac{\partial \sigma_x}{\partial x} + \frac{\partial \tau_{xy}}{\partial y} = 0 \quad \frac{\partial \tau_{xy}}{\partial x} + \frac{\partial \sigma_y}{\partial y} = 0 \quad (43)$$

These are the differential equations that have to be solved if the state of stress in the material during extrusion is to be obtained. In order to reduce the number of unknowns, σ_x, σ_y and τ_{xy} are substituted with p and ϕ in accordance with Eq. 42:

$$\begin{aligned} \frac{\partial p}{\partial y} + 2k \left(\cos 2\phi \frac{\partial \phi}{\partial x} + \sin 2\phi \frac{\partial \phi}{\partial y} \right) &= 0 \\ \frac{\partial p}{\partial y} + 2k \left(\sin 2\phi \frac{\partial \phi}{\partial x} + \cos 2\phi \frac{\partial \phi}{\partial y} \right) &= 0 \end{aligned} \quad (44)$$

The Eq. 44 may be described as hyperbolic. In such a case, solutions for p and ϕ can be obtained in parts of the xy -plane merely by solving a simplified version of the equations of interest along certain curves that cross a line, along which a boundary condition is prescribed. The lines of interest are called characteristics and are defined as curves in the xy -plane, across which the derivatives of p and ϕ may be discontinuous. It turns out that for this problem there are two distinct and perpendicular

Fig. 40 (a) The slip lines in relation to the cartesian coordinate system; (b) State of stress in a material particle

characteristics going through each point, having slopes $\tan\phi$ and $-\cos\phi$ to the x -axis. Thus, in the slip line analysis, the α - and β -lines are actually the characteristics of interest. If the state of stress is given at a certain boundary, it will also be uniquely defined in all points of the xy - plane which share both its characteristics with the boundary line (Fig. 41a). Thus, some peculiarities exist. It turns out the state of stress will not be influenced by conditions on other parts of the boundary of the material. Furthermore, by the definition of characteristics, the state of stress or any other field may change abruptly when crossing the α - or β -lines. These observations, however, are actually in accordance with the understanding of plastic deformation.

The velocity distribution in the flowing metal may be calculated only if isotropy and incompressibility is assumed:

$$\frac{2\dot{\gamma}_{xy}}{\dot{\epsilon}_x - \dot{\epsilon}_y} = \frac{\tau_{xy}}{\sigma_x - \sigma_y} \quad \frac{\partial v_x}{\partial x} + \frac{\partial v_y}{\partial y} = 0 \quad (45)$$

By introducing the Eq. 42 in the isotropy condition, a , the following relation may be obtained:

$$\cos 2\phi \frac{\partial v_x}{\partial x} + \sin 2\phi \frac{\partial v_x}{\partial y} + \sin 2\phi \frac{\partial v_y}{\partial x} - \cos 2\phi \frac{\partial v_y}{\partial y} = 0 \quad (46)$$

The velocity equations are also hyperbolic, and the characteristics of stress and strain are found to coincide at all points due to isotropy. Thus, the characteristic directions are those of both maximum shear stress and strain.

Both equations of stress and of velocity should be solved in the coordinate system defined by the slip lines. If it is assumed that the x and y directions at a particular point are oriented along the tangents to the α - and β -lines, the angle ϕ may be set to zero, rendering Eq. 44:

$$\frac{\partial p}{\partial x} + 2k \frac{\partial \phi}{\partial x} = 0 \quad \frac{\partial p}{\partial y} - 2k \frac{\partial \phi}{\partial y} = 0 \quad (47)$$

Since the original point chosen was arbitrary, the relations will hold at any point. If the Eq. 47 are integrated along

α - and β -lines respectively, the relation between the hydrostatic pressure p and the orientation, ϕ , of the slip line field relative to a rigid x -axis is:

$$\begin{array}{ll} \text{Constant along an } \alpha \text{ - line:} & \text{Constant along a } \beta \text{ - line:} \\ p + 2k\phi = C_1 & p - 2k\phi = C_2 \end{array} \quad (48)$$

These are the Hencky equations, which simply represent equilibrium along a slip line. It can be observed that the hydrostatic pressure will not change along a straight line. Generally p will vary along a curved line, the result being that the center of the Mohr-circle is translated along the σ -axis.

If the velocity equations are viewed in a coordinate system with axes tangential to the slip lines, the rate of extension vanishes along the slip lines:

$$\left(\frac{\partial v_x}{\partial x} \right)_{\phi=0} = \left(\frac{\partial v_y}{\partial y} \right)_{\phi=0} = 0 \quad (49)$$

If u and v are the velocity components along the slip lines, the velocity components along the x - and y - coordinate axes can generally be expressed as:

$$v_x = u \cos \phi + v \sin \phi \quad v_y = u \sin \phi + v \cos \phi \quad (50)$$

By substituting Eq. 50 into 49 and setting $\phi = 0$, differential relations along the slip lines are obtained:

$$\begin{array}{ll} \text{Along an } \alpha\text{-line:} & \text{Along an } \beta\text{-line:} \\ du + v d\phi = 0 & dv + u d\phi = 0 \end{array} \quad (51)$$

These are the Geiringer equations.^[59] Even though incompressibility is assumed, the velocity component tangential to a slip line may change. Such a variation is introduced by the curving of the slip lines. A constant tangential velocity along a slip line can be expected if the slip line is straight or if the velocity component normal to the slip line is zero. The last is the case for curved slip lines marking the boundary between flowing metal and dead zones.

Fig. 41 (a) Area with uniquely defined slip line solution; (b) Mikhlin-coordinates, ξ , $\bar{x}$ and η , $\bar{y}$ in relation to slip line grid

Velocity discontinuities can be expected to be present when the hyperbolic equations are solved. Since mass has to be conserved the velocity component normal to a line of discontinuity can not alter when passing it. The tangential component, however, may change (Fig. 41b). Hence, the discontinuity line may be looked upon as one alone which the rate of shear is infinite. The discontinuity line will then also be a slip line. Along such a line the change in tangential velocity will be constant.

Two theorems that are of practical interest when a slip line field is to be drawn are Hencky's first and second theorem. These follow directly from the Hencky equations. The first states that the following relations can be taken to hold for the values of ϕ and p in the point A, B, C and D on the Fig. 41b:

$$\phi_C - \phi_D = \phi_A - \phi_B \quad p_C - p_D = p_A - p_B \quad (52)$$

Thus, when going from one slip line to another in the same family the angle turned and the pressure change will always be the same.

Hencky's second theorem is based on the first and states that the curvature of lines of the other family decreases in proportion to the distance travelled along a slip line. If R and S are the curvatures along the α - and β -lines respectively and S_α and S_β the corresponding coordinates, the theorem yields:

$$\frac{\partial R}{\partial S_\beta} = -1 \quad \frac{\partial S}{\partial S_\alpha} = -1 \quad \Rightarrow$$

$$\begin{array}{ll} \text{Along an } \alpha \text{ - line :} & \text{Along an } \beta \text{ - line:} \\ dS + Rd\phi = 0 & dR + Sd\phi = 0 \end{array} \quad (53)$$

The last is a result of the mere definition of curvature. As can be seen, the curvature will decrease steadily as one moves to the concave side of the slip line. If the plastic zone extends sufficiently far, the radius of curvature finally vanishes. Discontinuities may, however, exist. The differential Eq. 53 are of the same form as 51. Furthermore, by moving along the slip lines, the Mikhlin coordinates shown in Fig. 41b, will change according to an equation of the same form:

$$\begin{array}{ll} \text{Along an } \alpha \text{-line:} & \text{Along an } \beta \text{-line:} \\ d\bar{y} + \bar{x}d\phi = 0 & d\bar{x} + \bar{y}d\phi = 0 \end{array} \quad (54)$$

The equations of the slip line theory can either be solved analytically, numerically or graphically. Complete analytical solutions are available for only a few problems. An example that will be provided is the process of frictionless plane strain extrusion at $R = 3$. If an area is determined uniquely by the stress boundary conditions, however, the pressures and slip line directions at a point (m,n) can be

determined directly from known values at neighboring points by the Hencky equations:

$$p(m, n) = p(m, n-1) + p(m-1, n) - p(m-1, n-1) \quad (55)$$

$$\phi(m, n) = \phi(m, n-1) + \phi(m-1, n) - \phi(m-1, n-1) \quad (56)$$

The velocity field and the geometry of the slip line field have to be calculated with the help of Eqs. 51, 53 and 54 within the area that is defined uniquely by the boundary solutions. If the slip-lines are curved at all points a closed form solution may be obtained by combining each pair of equations to the equation of telegraphy:

$$\frac{\partial^2 f}{\partial \alpha \partial \beta} = f \quad (57)$$

f may in this case be either the velocities, curvatures or Mikhlin variables. α and β are the coordinates along the slip lines and are related to ϕ as $\phi = \phi_o - \alpha + \beta$ where ϕ_o is a reference. Depending on the curvatures of the slip lines, a solution giving the form of the field and the velocities will be provided by either the modified Bessel function of the first kind or the Bessel function of first kind:

$$\begin{aligned} f(\alpha, \beta) &= \sum_{n=0}^{\infty} [\alpha_n f_n(\alpha, \beta) + c_n f_{n+1}(\beta, \alpha)] \\ f_n(\alpha, \beta) &= \left(\frac{\alpha}{\beta} \right)^{n/2} I_n(2\sqrt{\alpha\beta}) \end{aligned} \quad (58)$$

$$\begin{aligned} f(\alpha, \beta) &= \sum_{n=0}^{\infty} [\alpha_n g_n(\alpha, \beta) + c_n g_{n+1}(\beta, \alpha)] \\ g_n(\alpha, \beta) &= \left(\frac{\alpha}{\beta} \right)^{n/2} J_n(2\sqrt{\alpha\beta}) \end{aligned} \quad (59)$$

The constants will then be determined from the boundary conditions.

As the analytical solution may be hard to perform, the geometry of the slip line field may be calculated numerically by the discretisation of the Eq. 54. A constant angular distance in both α - and β - direction is chosen. The values of the Mikhlin coordinates in a point (m,n) are then calculated as those in neighboring points (m,n-1) and (m-1,n) are already known.

$$\bar{x}(m, n) - \bar{x}(m, n-1) = \frac{1}{2} [\bar{y}(m, n) + \bar{y}(m, n-1)] \mu \Delta \phi \quad (60)$$

$$\bar{y}(m, n) - \bar{y}(m-1, n) = \frac{1}{2} [\bar{x}(m, n) + \bar{x}(m-1, n)] \lambda \Delta \phi \quad (61)$$

μ and λ are either -1 or 1 depending on whether $\Delta\phi$ decreases or increases when going from the neighboring points. The velocity field can be found in the same manner.

A complete geometrical slip line solution is provided by Prager's method^[60] (Fig. 42). As three aspects are of interest, the stress state, the velocity distribution and the geometry of the slip line field, it seems natural to generate three geometrical representations, the stress plane, the hodograph and the physical plane. The stress plane consists of a number of Mohr's circles, representing the state of stress at all points in the material. As the material is assumed to yield, all states provide circles with the same radius, k . The position of the pole will then be of primary interest since it will characterize the state of stress. When one moves along a curved slip line, the stresses are observed to change and consequently also the position of the pole. Lines showing its movement can then be drawn in the stress plane. The lines corresponding to the movement along an α - and β -lines are the cycloids that would be generated if the Mohr-circle had rolled without slipping on the lines $\tau = k$ and $\tau = -k$. More importantly it can be shown that their form corresponds to the form of the slip lines in the physical plane.

The hodograph is simply a representation of the velocity vectors at each point in the physical plane. The vectors are constructed from the same point so that the changes in velocity between two points will be given by the vector drawn between their arrow heads. An important property is that while the slope of the α -line is $\tan \phi$, the relation $\frac{dv_y}{dv_x}$ will be $-\cot \phi$ along the line. Hence, the vector giving the change in velocity at a point will be directed normal to the slip lines. This is in accordance with the fact that no elongation will be expected along the slip lines.

Frictionless Extrusion with $R = 3$

A simple analytical slip line solution may be obtained if it is assumed that extrusion of $R = 3$ with no friction forces along the container wall and die is performed as shown in Fig. 43a. The problem is regarded as one

of steady state. A velocity is prescribed for the piston. Other boundary conditions are assumed to be expressed in terms of stress. Neither a bearing channel nor a puller is included in the analysis. Therefore the material will be free from tractions at the die opening, $\sigma_x = 0$ and $\tau_{xy} = 0$. It may then be seen that some kind of discontinuity must exist since equilibrium does not allow the stress component along the x -axis to be zero for the material close to the die. The solution is the construction of a fan field since this allows an abrupt change in the hydrostatic pressure along a given line.

If it is assumed that the state of stress in zone I is one of yielding, it can be determined uniquely by the boundary conditions. The Mohr circle reveals that the stress component $\sigma_y = -2k$. As a result the lines of maximum shear must be inclined at an angle of $\frac{\pi}{4}$ and $-\frac{\pi}{4}$ to the x -axis.

Hencky's first theorem indicates that both the angle ϕ and the hydrostatic stress, $p = k$, will be uniform in zone I, and therefore it will have the form of a triangle with straight edges.

In zone II the α -lines are taken to be radial and β -lines tangential. As the radial lines are straight, the hydrostatic pressure can be expected to be uniform along these lines. A singularity will then exist at the point where the radial lines run together, the presence of a sharp edge being the cause. Along the β -lines the expression $p - 2k\phi$ is constant.

If ϕ is chosen to be $-\frac{\pi}{4}$ at the boundary between zone I and zone II where $p = k$, the pressure along an arbitrary β -line will be $p = k + k\frac{\pi}{2} + 2k\phi$. The boundary to zone III will be a straight line at $\phi = \frac{\pi}{4}$. The reason is that the characteristics also in this region must be straight and inclined at an angle $\frac{\pi}{4}$ and $-\frac{\pi}{4}$ due to the boundary condition $\tau_{xy} = 0$ at the die. Hence, the hydrostatic pressure increases from k to $k(1 + \pi)$ from region I to III. This corresponds to a movement of the center of the Mohr circle a distance $k\pi$ to the left. The coordinate stresses in region III may then be calculated to be:

Fig. 42 Slip line solution by Prager's method: (a) The physical plane; (b) The stress plane; (c) The hodograph

$$\sigma_x = -p - k \sin 2\phi = -k(1 + \pi) - k \sin 2\frac{\pi}{4} = -2k\left(1 + \frac{\pi}{2}\right) \quad (62)$$

$$\sigma_y = -p - k \sin 2\phi = -k(1 + \pi) - k \sin 2\frac{\pi}{4} = -k\pi \quad (63)$$

$\tau_{xy} = 0$ in accordance with the boundary condition and Hencky's first theorem. These results can also be obtained graphically through Fig. 43c. The stress component σ_x constitutes the pressure experienced by the die.

The velocity field may then be calculated. The material to the left of the plastic zone is assumed to be rigid and

Fig. 43 Slip line solution for indirect extrusion at $R = 3$. (a) Geometry and slip line grid; (b) The hodograph (velocity field) and the flow lines; (c) The state of stress

is therefore expected to move with the same velocity, V , as the stem. Since the incompressibility condition can be expected to hold, the velocity of the extruded profile will be $R \times V$. The straight characteristics of region I indicate a uniform velocity of the same magnitude in the x -direction. In region III the material must flow along the die surface. Since the characteristics are straight also in this region, one must expect that the velocity is uniform. The line that separates region III from the rest of the container, must then be a velocity discontinuity. As expected, this is also a slip line. The change in flow velocity will be directed tangentially to the discontinuity line and be $\sqrt{2}V$ (Fig. 43b). As can be seen, the flow velocity in region III will also be V .

The remaining question is then how velocity changes take place in the fan. The simplest way to answer this is by constructing the hodograph (See Fig. 50b). The velocity vectors representing region I, III and IV are drawn first. The vector representing the discontinuity between the regions III and IV is then added, confirming assumptions made earlier. One should notice, however, that the magnitude of a velocity discontinuity is constant along a characteristic. Therefore, the velocity discontinuity at each point along the outer β -characteristic may be drawn as a radial line with a length $\sqrt{2}V$ starting from the end of velocity vector of region IV. The circle sector generated in the hodograph will span the same angle, $\frac{\pi}{2}$, as the sector in the physical plane. Thus, there must also be a velocity discontinuity of the same magnitude on the border between the fan and region I. As expected, the geometry of the hodograph resembles that of the characteristics in the physical plane.

The main objective with using the slip line theory is to obtain a simple mathematical description of the flow paths and deformation history. The uniform flow velocity in regions I, II and IV may easily be described by constant components in the x and y direction. In order to obtain expressions for the velocity in region II one has to apply the Geiringer equations. In polar coordinates the criterion of no elongation along stream lines may be written as:

$$\dot{\epsilon}_r = \frac{\partial v_r}{\partial r} = 0 \quad \dot{\epsilon}_\phi = \frac{\partial v_\phi}{r \partial \phi} + \frac{v_r}{r} = 0 \quad (64)$$

The first equation confirms that the radial velocity only will be function of the angle ϕ . As no radial discontinuity in velocity can be allowed for a material particle going from the outer field and into the fan, v_r must be cosine function which yields $-V$ for $\phi = 0$. The second of Eq. 64 may then be solved with the boundary condition $v_\phi\left(\frac{\pi}{4}\right) = -\sqrt{2}V$.

The velocity components in the fan are then:

$$v_r = -V \cos \phi \quad v_\phi = V \sin \phi - \sqrt{2}V \quad (65)$$

The shear strain rate and equivalent strain rate may be calculated from the above expressions:

$$\dot{\gamma}_{r\phi} = \frac{1}{r} \frac{\partial v_r}{\partial \phi} + \frac{\partial v_\phi}{\partial r} - \frac{v_\phi}{r} = \sqrt{2} \frac{V}{r} \quad \dot{\epsilon} = \frac{\dot{\gamma}_{r\phi}}{\sqrt{3}} = \sqrt{\frac{2}{3}} \frac{V}{r} \quad (66)$$

By the help of the definition of radial and tangential velocity, the flowline through the fan for a particle starting at (r_0, ϕ_0) on the boundary may be calculated:

$$\frac{v_r}{v_\phi} = \frac{dr}{rd\phi} = \frac{-V \cos \phi}{V \sin \phi - \sqrt{2}V} = \frac{\frac{1}{\sqrt{2}} \cos \phi}{1 - \frac{1}{\sqrt{2}} \sin \phi} \quad (67)$$

Integration and use of the of the known starting point (r_0, ϕ_0) at an edge of the fan provides the equation for the flowline:

$$r = r_0 \frac{\sqrt{2} - \sin \phi_0}{\sqrt{2} - \sin \phi} \quad (68)$$

Some of the possible flowlines are shown in Fig. 43b. If such a line enters fan at r_0 on the characteristic $\phi = \frac{\pi}{4}$, the ratio r/r_0 will be independent of the value of r_0 . This is due to the lack of variation in particle velocity along an α -characteristic. As a result, all such flowlines in the fan have the same form. By inserting data one finds that $r < r_0$ for all ϕ except when $r = r_0 = 0$. This is accordance with the fact that the material is compressed during extrusion.

The study of deformation of rectangular grid patterns constructed on the billet proves valuable as it opens for a comparison of the experimental and analytical results. Furthermore, emptying diagrams, which can be derived numerically, may also provide information about the origin of material particles in the profile. Thus, at least qualitative data on the deformation of material particles and the danger of inferior surface quality due to the inflow of particles from the billet surface, may be obtained through the use of slip line theory. If one is to relate the position of a particle in the billet to that in the extruded profile, one has to calculate both the coordinates of the path-line and time spent on travelling along the line. As material particles in all but the fan region are expected to run along straight lines with a prescribed velocity, most of the necessary calculations are trivial. In the fan, Eq. 68 describes the flowlines. The corresponding expression for the time needed for a particle to travel from one point on the flowline to another, must be derived from the definition of tangential velocity, $\frac{v}{r} = \frac{d\phi}{dt}$. An integration then results in:

$$\begin{aligned}
 t &= \int_{\phi_0}^{\phi} \frac{r}{v_{\phi}} d\phi = -\frac{r_0}{V} (\sqrt{2} - \sin \phi_0) \int_{\phi_0}^{\phi} \frac{d\phi}{(\sqrt{2} - \sin \phi)^2} \\
 &= \frac{r_0}{V} (\sqrt{2} - \sin \phi_0) \\
 &\quad \left[\frac{\cos \phi}{\sqrt{2} - \sin \phi} - 2\sqrt{2} \arctan \left(\sqrt{2} \tan \frac{\phi}{2} - 1 \right) \right]_{\phi_0}^{\phi} \quad (69)
 \end{aligned}$$

where ϕ_0 and ϕ are the angles marking respectively the start- and the endpoints of the flowline. In order to calculate the time spent on going through the whole fan, one must set $\phi = -\frac{\pi}{4}$ and (r_0, ϕ_0) either equal to $\left(r_0 < R, -\frac{\pi}{4}\right)$ or $\left(R, -\frac{\pi}{4} < \phi_0 < \frac{\pi}{4}\right)$ depending on the boundary section of the fan crossed.

Figure 44a reveals the geometry of the calculation model. The deformation of a straight line starting at $x = 2L$ is then studied by calculating the time taken for a particle to flow from the line to various points and then drawing iso-time curves. In the region denoted IV, the material will move uniformly and the line will remain straight until a part of it touches the fan. The material in the fan will then accelerate, and due to the geometry of the fan field a part of the line at a short distance from the centerline will move forward relative to line segments both on the left and the right side. Particles on the centerline will experience a sudden increase in velocity when entering region I. However, it turns out that some particles that have been accelerated

through the fan on the average will move the fastest, and, thus, constitute the most forward part of the iso-time curve in the profile. The particles close to the container walls will be delayed due to the long distance they have to travel. Since zero friction conditions are assumed, however, material from the container surface will eventually reach the profile surface and potentially cause poor surface quality. Dead zones will not be present. The last observation is confirmed by Fig. 44b, which is the emptying diagram for the model used. The diagram is obtained by calculating the time each particle in the container will need to reach the die opening of container. Iso-residence-time curves are then drawn. The two diagrams presented essentially give the same description of the extrusion process.

If it is assumed that extrusion is performed with a high flow rate, heat transfer will mainly be convective and the temperature of a particle will at any point be proportional to the amount of heat received. Conditions are then assumed to be adiabatic. As a material is deformed, the energy spent on deforming it will either be stored in the microstructure through a high dislocation density or dissipated as heat. In the case of cold working the first part will not amount to more than about 5%. As both work hardening and recovery/recrystallization take place during extrusion the dislocation density does not necessarily increase and therefore the part of the energy stored in the microstructure may be neglected. As a result one may roughly state that the increase in thermal energy of a particle will be equivalent to the heat provided by dissipation:

$$pc\dot{T} = \alpha_{ij}\dot{\epsilon}_{ij} = \bar{\sigma}\dot{\epsilon} \quad (70)$$

Fig. 44 Material deformation in extrusion with $R = 3$ and $v_0 = 0.05$ m/sec. All times in seconds. (a) The deformation of a line which is straight at $x = 2L = 0.2$ m and $t = 0$ s; (b) The emptying diagram; (c) Velocity vectors

where ρ is the density and c the heat capacity. The temperature will increase through the fan and when crossing a velocity discontinuity. In the areas where the material moves with a uniform velocity, no strain rates are expected and therefore no increase in temperature either. An analytic expression for the rise in temperature through the fan is obtained by performing an integration of Eq. 70 with respect to the time spent on travelling from one point, (r_0, ϕ_0) , to another, (r, ϕ) . Equation 66 is an expression for the equivalent strain, and Eqs. 68 and 69 must be applied as they describe the path followed and relate the time increment to an increment in the angle, ϕ . If k is taken to be constant, an expression for the difference between the temperatures at two points in the fan is:

$$T - T_0 = \int_{t_0}^t \frac{\bar{\sigma}}{\rho c} \dot{\epsilon} dt = \sqrt{\frac{2}{3}} \frac{\bar{\sigma}}{\rho c} \int_{t_0}^t \frac{V}{r} dt = \sqrt{\frac{2}{3}} \frac{\bar{\sigma}}{\rho c} \int_{\phi_0}^{\phi} \frac{1 - \sqrt{2} \sin \phi}{\sqrt{2} - \sin \phi} - 2 \frac{\sec^2 \phi (\sqrt{2} - \sin \phi)}{1 + \left(\sqrt{2} \tan \frac{\phi}{2} - 1 \right)^2} dt \quad (71)$$

If $\bar{\sigma} = \sqrt{3}k$ and integration is performed the result is:

$$T - T_0 = 2\sqrt{2} \frac{k}{\rho c} \left(\arctan \left(\sqrt{2} \tan \frac{\phi_0}{2} - 1 \right) - \arctan \left(\sqrt{2} \tan \frac{\phi}{2} - 1 \right) \right) \quad (72)$$

The adiabatic temperature change through the fan is only dependent on the point where the material enters and on the total angle turned. In other words, an increment of temperature change will only depend on the increment of change in angle. The material that enters the fan at the angle $\phi = \frac{\pi}{4}$ will experience a temperature rise that is independent of r_0 , and, therefore, the material closest to the surface will leave with a uniform temperature. Even though the value of the strain rate goes to infinity for small radii, temperature changes will be limited as the time spent in the fan approaches zero. If, however a material particle enters the fan at an angle $\phi_0 < \frac{\pi}{4}$, the increase in temperature through the fan will be smaller, and the material in the center of the profile can be expected to be colder than that on the surface.

Velocity discontinuities represent areas of concentrated shear. If it is assumed that the discontinuity has a certain thickness, δ , the strain rate experienced by a particle

going through a discontinuity will be $\dot{\gamma} = \frac{\Delta v}{\delta}$ where Δv is the sudden change in velocity tangentially to the discontinuity. The time spent on passing the discontinuity will be $\Delta t = \frac{\delta}{v_n}$ where v_n is the component of the velocity normal to the discontinuity line. The total straining of a material particle going through the discontinuity will then be $\gamma = \dot{\gamma} \cdot \Delta t = \frac{\Delta v}{v_n}$. On the discontinuity between region III and IV v_n can be expressed as:

$$\Delta \gamma = \frac{\Delta v}{v_n} = \frac{V\sqrt{2}}{V\sqrt{2}} = 2 \quad (73)$$

In the same way the discontinuities between the regions I and II and II and IV can be shown to give the total strain of respectively $\frac{2}{3}$ and $\sqrt{\frac{2}{\cos \phi}}$. The rise in temperature due to a number of velocity discontinuities can be calculated to be:

$$\Delta T = \frac{k \Sigma \Delta \gamma}{\rho c} \quad (74)$$

If it is assumed that the billet originally has a uniform temperature of 450°C, the adiabatic temperature at a certain point may be calculated simply by adding the contributions from all areas of shear the particle at the point has passed. The result is shown in Fig. 45a. In reality, both friction at the container wall and at bearing surfaces will contribute to even higher temperatures close to the surface of the profile. The adiabatic assumption may also often prove to be not entirely correct, and as a result, the temperatures at least in the profile leaving the container may be lower and more uniform than expected.

Alternative Slip Line Fields

The motivation for choosing a case with an R -ratio of 3 and frictionless conditions is mathematical simplicity and not the model's coherence with reality. Extrusion usually takes place at R -ratios that can be many tenfolds larger than 3, and due to the presence of friction, the velocity fields differ significantly from the one proposed. However, as the extrusion process traditionally has been a popular test case for the application of theory, a large number of analytical and semi-analytical slip line solutions have been found. Books on the classical slip line theory^[61,62] present quite a few problems with different assumptions connected to friction and reductions.

Figure 46 gives an example of a slip line field in the case where there is sticking friction between the flowing metal and the tooling. If the friction model is to be that of Tresca, the shear stress between the container wall and the

Fig. 45 (a) Temperatures given under adiabatic conditions with billet preheated to 450°C; (b) Hydrostatic pressure during extrusion [MPa]

Fig. 46 Slip line field for the direct extrusion of aluminum under the assumption of full sticking at the walls of the container and the die

flowing metal is equal to the shear yield stress of the metal. As this is also the maximum shear stress possible, the slip lines that interfere with the walls have to be either normal or tangential to it except at singularities. The slip lines of both families also have to meet the center axis at an angle of $\pi/4$ due to the symmetry condition. The slip line field may then be calculated both analytically and numerically as earlier described.

When applying numerical methods the slip lines in the grid should be separated by a constant increment of the angle, $\Delta\phi$. The geometry of the container, particularly the R -ratio, will uniquely determine the angle between the outermost radial lines of the fan. If R reaches about 12.5, the analysis breaks down as the upper radial line then is tangential to the surface of the die. When the slip line field is determined, the stresses follow directly from Hencky's equations. The coordinates in a xy -system may be calculated by starting at the fan and working outwards under the assumption that the line segment between two nodes is approximately straight.

In order to obtain the velocity field, the boundary conditions have to be determined. The material to the right of the slip line field is assumed to move uniformly at the pace of the piston. This can be used to calculate the velocity components along the velocity field in the rightmost part of the slip line field. In the dead zone the material velocity is expected to be zero, and velocity components normal

to the closest slip line vanish. Consequently the velocity tangential to this slip line is constant and equal to the velocity of the piston, which then also is the magnitude of the velocity discontinuity along the line. A last boundary equation is that the components of velocity along the symmetry line must be equal as it is a flowline. In order to obtain a numerical solution to the problem a discrete form of the Geiringer equations have to be applied. The values of the components of velocity in a node are then found from the corresponding values in the neighboring nodes. By a method of trial and error, the velocity components at all points on the symmetry lines are varied until all boundary conditions are satisfied simultaneously.

The Slab Method Applied in the Study of Friction on Bearing Surfaces

The strip or slab method, which is a part of the elementary plasticity theory, is based on a simplified view of the state of stress in the material. Usually only conditions of plane strain are considered. The work piece is directed along an axis, say the x -axis, and then divided into a number of infinitesimally thin strips, each with a thickness dx . These are studied individually. In order to make this division worthwhile one has to neglect all other velocity components than that along the x -axis. At the same time one assumes that the principal directions of stress and strain are along

the coordinate axes. Differential relations describing both the velocity field and the stress field may then be obtained simply by asserting that the equations of conservation of volume and motion in x -direction have to be satisfied. The relation between different components of stress is obtained through the Tresca yield criterion.

The slab method has been applied on a range of problems connected to materials forming, such as drawing, rolling, forging and extrusion. The results obtained are usually the forming forces, which strictly must be taken to be lower bounds as the method is based on equilibrium considerations. However, the slab methods will at best only give a simplified view of the stresses and deformation in the metal and at worst provide totally erroneous results. This is especially the case when the slab method is applied in the study of the relatively complex flow in the container during extrusion, as the assumption regarding the principal directions of stress need not be correct. Another problem is that the slab method does not accept large changes in geometry along the x -axis because the analysis then will be inconsistent. The extrusion force may be calculated to be in accordance with the relation $F = a + b \ln(R)$ also with the slab method, but one must be aware of the fact that the method of calculation only guarantees the result in case of small values of the reduction ratio.

In relation to the extrusion process, the slab method may probably most effectively be applied in the study of the pressure build-up through the bearing channel. Usually, analytical solutions neglect the presence of such a channel all together, but in practical extrusion bearing surfaces of zero length are neither possible nor desirable. The pressure build-up caused by the friction between the flowing material and the bearing surfaces may actually be utilized to control the flow and therefore also the profile quality. The aim will then always be that the velocity in the cross-section of the profile leaving the die should be as uniform as possible and that no internal stresses should be generated. The general rule is that a material particle will flow in the direction of the lowest pressure gradient. If the material flows too fast over a certain part of the cross section as a result of low flow resistance, one must attempt to force the material flow in other directions by increasing the length of the bearing channel and thereby also the total friction force. As less material then is expected to enter the region, the flow speed is reduced and hopefully made more equal to that of neighboring parts of the cross section.

When bearing channels are not properly adjusted, as often is the case in connection with complex die geometry, the result will be unbalanced and uncontrolled flow, but not necessarily totally unusable products. If the material flows faster in parts of the cross-section, the profile can be expected to bend as it leaves the die. If velocity gradients perpendicular to the flow direction also exist during further extrusion, the profile walls may buckle or twist in

areas with too great speed and experience thinning or even tearing where the velocity is too low. However, as more of the profile is extruded the material will usually leave the die at an almost uniform speed. This is due to the fact that velocity gradients will cause shear stresses, which in the next turn will contribute to the reduction of such gradients. The result is that residual compressive stresses can be found in the parts of the profile that experienced the largest flow velocity in the bearing channel. Tensile stresses will be generated in slow flowing parts so that a force equilibrium eventually will exist. This self-stabilizing effect is present in a number of metal forming processes and explains why relatively satisfactory product quality can be obtained without total process control. However, complete reliance on such an effect is not desirable since the control of flow velocity in products with variable wall thickness and especially in thin-walled section is inefficient. Furthermore, residual stresses have to be properly removed by a stretching operation. This is particularly important if further operations such as for instance bending are to be performed on the profile.

The lengths of the bearing surfaces may be from a couple of millimeters to about a centimeter, and the surface area constitutes only a very small percentage of the total area of interaction between the flowing metal and the die. Furthermore, short bearing surfaces are generally preferred as they generate less friction and therefore reduce the need for a large extrusion force. However, even relatively short bearing lengths generate large increases in the needed extrusion pressure. And most importantly, the interaction between the flowing metal and the bearing surfaces is maybe the most complex and variable element of the extrusion process and, thus, can be expected to be of prime importance to product quality. As will be explained in the next section, the study of interaction between flow stability, die deflection and friction in the bearing channel is one of the most interesting fields of research.

A simple slab analysis will be performed in order to calculate a rough mean value for the pressure rise through the bearing channel due to the presence of friction. As will be explained later, one may assume that the flowing material sticks to the bearing surface over the first 4 mm and that the shear stress in the sticking region is constant and equal to the shear yield stress k . The friction close to the outlet will be of Coulomb type, and it is assumed that the shear stress in the slipping region decreases linearly from the slip point and towards the outlet. The last assumption is probably only correct if the normal stress to the bearing also can be expected to decrease towards the opening. The bearing surfaces are taken to be parallel at all points. Usually, bearing surfaces are either converging or diverging and are said to be designed with respectively a choke or a release. The establishment of the position of the slip point where material starts gliding along the bearings and a surface may be said to be created, represents the main problem. Even though experiments have confirmed the presence of such

a point, and its position has been determined for various choke angles, bearing lengths, alloys and extrusion rates, no rigorous method of estimation this parameter has yet been developed. Hence, when performing both analytical and numerical calculations, assumptions are usually made regarding the position of the transition region. This introduces an uncertainty into the analysis. In the following slab calculations (Fig. 47) the friction against the bearings will be described by the equations:

$$\begin{aligned} 0 < x < 4[\text{mm}]: \quad \tau &= 30 \quad [\text{MPa}] \\ 4 < x < 8[\text{mm}]: \quad \tau &= 55 - \frac{25}{4}x \quad [\text{MPa}] \end{aligned} \quad (75)$$

The slip point is, thus, assumed to be at $x = 4$ mm, and the shear stress at the opening is set to 5 MPa. Finally, the principal stress directions are chosen to be parallel to the coordinate directions. This is actually only correct near the x -axis, along which the coordinate shear stresses may be expected to vanish due to symmetry. Close to the bearing surfaces the presence of the boundary condition makes it evident that

the assumption regarding principal directions must be incorrect. However, if it is assumed that the inconsistencies may be neglected, a force equilibrium will yield a differential equation for the x -component of stress:

$$\left(\sigma_x + \frac{d\sigma_x}{dx} dx \right) \times 2s - \sigma_x \times 2s - 2\tau \times dx = 0$$

$$d\sigma_x = \frac{\tau}{s} dx \quad (76)$$

Integration from $x = 8$ to $x = 0$ mm then provides the stress along the bearing channel. First, the integration is performed from $x = L = 8$ mm to $x = x_s = 4$ mm with the assumption that $\sigma_x(L) = 0$. Then, $\sigma_x(x_s) = -70$ MPa is found and the data is used in the integration from $x = x_s$ to $x = 0$. The result is:

$$0 < x < 4[\text{mm}]:$$

$$\sigma_x(x) = \sigma_x(x_s) - \int_{x_s}^x 30 d\xi = -190 + 30x$$

$$4 < x < 8[\text{mm}]:$$

Fig. 47 Slab model of the material flow in the bearing channel. (a) The geometry of the model; (b) Variation in stresses and temperatures throughout the bearing channel ($L = 8$ mm); (c) Development of the temperature field in the bearing channel

$$\sigma_x(x) = \sigma_x(L) -$$

$$\int_x^L \left(55 - \frac{25}{4} \xi \right) d\xi = -\frac{25}{8} x^2 + 55x - 240 \quad (77)$$

From the criterion of full sticking and the above equations it may be seen that the stress component normal to the bearing surface will decrease linearly in the sticking region, which is in accordance with the assumptions made. At the inlet to the bearing channel the x-component of normal stress is then calculated to be -190 MPa. This result may be used as a rough estimate in a slip line analysis.

The slab method may also yield a rough estimate of the temperature increase through the bearing channel. The y-axis is assumed to be directed normal to the bearing surfaces. As heat will be generated on the surface between the flowing metal and the die it is natural to expect that the temperatures of greatest magnitude may be found in this area. At the same time, the temperature will increase steadily towards the outlet of the bearing channel. A simple approximate temperature field can be assumed to satisfy the relation:

$$T = T_s + \Delta T \left(\frac{y}{s} \right)^2 \quad (78)$$

where $2s$ is the width of the bearing channel, and the parameters T_s and ΔT are only dependent on x . It is then assumed that all heat generated on the boundary between the die and profile will contribute to an increased temperature in the profile and that heat conduction only will take place in the y-direction. Thus,

$$q_y = -\lambda \left(\frac{dT}{dy} \right)_{y=s} = \frac{2\lambda \Delta T}{s} = -\tau v \quad (79)$$

$$\Delta T = \frac{v \times s}{2\lambda} \tau$$

where v is the extrusion speed and τ is the shear stress on the boundary. ΔT will then be a function of τ and therefore also x . In this example the following material parameters are used: $w = 1$ m/sec, $\lambda = 200$ W/mK, $\rho = 2700$ kg/m³ and $c = 1100$ W/mK. For $x < 4$ mm ΔT will be constant and equal to the original value of 75°C since the shear stress is constant. From $x = 4$ to $x = 8$ mm the value of ΔT will decrease linearly to 12.5°C at the outlet due to decreasing τ . Since the heat generation connected to friction will be spent on increasing the temperature, T_s must be expected change along x . As ΔT will not be altered for $x < 4$ mm, all heat added will contribute to the increase of T_s . The heat balance for an element is then:

$$-q_y dx dt = \rho c dT_s dx \quad T_s(x) = \frac{q_y x}{\rho c s v} = 10.1x \quad (80)$$

x is given in millimeters. As only changes in temperatures are to be assessed, $T_s(0)$ is set to 0, and the value of T_s at $x = 4$ mm can be calculated to be 40.4°C . A similar equation may be derived from the heat balance in the case where ΔT varies along x :

$$-q_y dx dt = \rho c \left(dT_s + \frac{1}{3} d\Delta T \right) s dx \quad (81)$$

The term $\frac{1}{3}$ is due to the parabolic ΔT -distribution. Integration and substitution of $q = -\tau v$ then yield:

$$T_s(x) = T_s(x_s) + \frac{1}{3} \Delta T(x_s) - \frac{1}{3} \Delta T(x) + \frac{1}{\rho c s} \int_{x_s}^x \tau(\xi) d\xi \quad (82)$$

In the present example a closed form solution can be reached if the functions $\Delta T(x)$ and $\tau(x)$ are inserted. x is to be given in millimeters.

$$T_s(x) = -37.67 + 23.73x - 1.05x^2 \quad (83)$$

The temperature in the middle of the profile at the outlet ($x = 8$ mm) may thereafter be calculated to be approximately 84.8°C . As expected the temperature in the mid-section of the profile has risen through the bearing channel, but the transversal temperature gradients are reduced due to the decreasing amount of dissipation through friction in the slipping zone. If x and y still are taken to be in millimeters, the total temperature function may be written:

$$T(x, y) = 10.1x + 75y^2$$

$$T(x, y) = -37.67 + 23.73x - 1.05x^2 + 2.5 \left(55 - \frac{25}{4}x \right) y^2 \quad (84)$$

The curves for $T(x, 0)$ and $T(x, 1)$ are given in Fig. 47. Here, it is assumed that $T_s(0) = 500^\circ\text{C}$ and not 0.

Numerical Analysis

A complete analytical description of the extrusion process is of interest since it simplifies parameter studies, and since numerical results can easily be obtained and therefore also applied in on-line process control. However, such solutions are rarely found for more complex geometries with multi-axial stress and strain-states, and will only under the simplifying assumption of adiabatic conditions yield a proper estimate on both the strain rate and temperature history. Today, it seems as the most satisfactory alternative or complement to closed form solutions has been provided by the finite element method (FEM).^[63–65]

A FEM solution for a plastically deforming material is, however, nothing but an upper bound solution, as the method utilizes the calculation of work done on the volume of the elements during a virtual deformation. The main difference between a numerical and an analytical approach is that fewer elements usually are applied in the later, and therefore, that the corresponding kinematically admissible velocity field provides a higher upper bound. If one assumes that the material model and boundary conditions give an accurate description of reality, a numerical method will in the very limit of infinitesimal elements both yield a solution which is correct and continuous. Such is evidently inachievable as the number of elements and therefore also the computation time would be infinite. Presently, the numerical codes for axisymmetric and plane strain solutions work satisfactorily, and some approaches have been made in order to solve problems of the full three dimensions.

Undoubtedly, the finite element method constitutes a valuable tool when one is to simulate both continuum thermo-mechanical and metallurgical aspects of the extrusion process.^[66,67] The approach, however, has to be indirect as the FEM method does not address problem at micromechanical level. Firstly, constitutive relations such as that of Zener-Hollomon may be determined experimentally, and one should therefore theoretically be able to predict material behavior with the help of the principles of metallurgy. Furthermore, material anisotropy may be determined from metallurgical studies, and such information may in theory, even though still not in practice, be implemented in a numerical code. Shorter routines for calculation of changes in the microstructure of the material after and during extrusion may also be added to the FEM-program. The elongation, shearing and rotation of grains can then be calculated through a Taylor-analysis,^[68] and although the theoretical fundament of this approach is far from flawless, experiments tend to give results in fair accordance with calculations. By obtaining information about stain, strain rate and temperature history of each particle one should also be able to assess the degree of recrystallization and changes in dislocation density.

Numerical modeling of extrusion also has other advantages to analytical calculations. Since conduction of heat may be simulated, one need not limit the analysis to one of large extrusion rates and adiabatic conditions.^[69] Furthermore, the equilibrium and energy equations may be solved simultaneously, the result being that one manages to capture the strong two-way thermo-mechanical coupling inherent in the equations. Whereas simpler calculations may be performed so that the temperature field is affected by mechanical dissipation, one will hardly be able to model the temperature's influence on the constitutive relation. Consequently information on the softening effect on material during extrusion is lost in analytical calculations. One may, however, argue that calculations with one way coupling and a perfectly plastic material model will

give results not far away from those provided by a more complete model. The reason for this is that larger strain rates and the higher temperature caused by increased dissipation, affect the shear yield stress in opposite directions. Furthermore, as shear deformation preferentially takes place on planes with the lowest shear resistance, there is some kind of a self-regulating mechanism, which establishes a state of quasi-equilibrium between the deformation and temperature field at all times. Even though it has not been proven, one may expect that the shear stress on the planes of deformation will approximately be a constant, a yield stress.

Numerical simulations are also advantageous in that they have the potential for capturing the thermo-mechanical interaction between the flowing metal and the tooling. Until now only two aspects of this coupling have been properly exploited, the description of friction on the bearings and on the container wall and the description of heat conduction between the tools and the aluminum. A solution of the complete heat conduction problem can only be found if the geometry of the stem, die and container is prescribed, the mode of heat exchange between the flow and the tools is determined and the temperature field is calculated by FEM. Various FEM-packages perform this calculation in a satisfying manner. Few numerical codes, however, provide solutions for deformation of and stresses in the die, container and stem, and since most programs only manage to describe plane or axisymmetric geometry, the solutions that exist, yield insufficient information for use for instance in the construction of dies.^[70] Full thermo-mechanical description of this coupling for three dimensional geometry would be valuable since it would increase the understanding of how the deformation of the die influences aspects of profile quality such as dimension and surface finish, and since it could be used as a tool for designing new dies and profiles. A study of such is today hindered by the extremely long calculation times for three dimensional codes and incomplete understanding of friction phenomena especially in the bearing channel.

$$\rho \left[\frac{\partial u_i}{\partial t} + (u_j - u_{0j}) \frac{\partial u_i}{\partial x_j} \right] = \frac{\partial \sigma_{ij}}{\partial x_j} \quad (85)$$

$$\rho c \left[\frac{\partial T}{\partial t} + (u_i - u_{0i}) \frac{\partial T}{\partial x_i} \right] = - \frac{\partial q_i}{\partial x_i} + s_{ij} \dot{\epsilon}_{ij} \quad (86)$$

Equations 85 and 86 are respectively the equations of motion and energy. ρ is the density of the material, $\mathbf{u}_0$ is simply a reference velocity. The total stresses σ_{ij} is composed of a deviatoric and a hydrostatic part, s_{ij} and $-p\delta_{ij}$ respectively. Equation 85 reveals that a numerical procedure takes the acceleration terms into account. This stands in sharp contrast to analytical solutions, which usually assume steady-state conditions. Such an assumption is, however, only satisfactory in the mid-part of the extrusion

charge. The extrusion process is transient in nature, and especially in the first and last parts of the extrusion run will a steady state assumption lead to numerical errors of some magnitude.

The description of the problem is, however, not complete as the constitutive relations are not defined. The usual assumption is that conduction is determined by Fourier's law, and a Zener-Hollomon relation may be applied in the mechanical equation. The last defines only a relation between shear stresses and strains, and the last equation of interest is that of incompressibility. Elastic effects may also be simulated, but as earlier explained calculations then tend to be more complicated.

An element formulation may then be reached by multiplying Eq. 85 by a virtual velocity, 86 by a virtual temperature and the incompressibility equation by a virtual pressure, applying the constitutive relations and then integrating over the complete volume of the element. A system of equations which yields the change in velocity, pressure and temperature over a time increment is then reached. If the temperature and velocity fields are to be solved simultaneously, calculation times may be very high. Instead equations of temperatures and velocities/pressures are often uncoupled and calculated separately by an iterative technique. The reference list provides an example of a system of equations for one element, which is solved in the numerical program ALMA2 π .^[71]

$$\begin{bmatrix} \mathbf{k}_{uu} & \mathbf{k}_{up} \\ \mathbf{k}_{up}^T & \mathbf{0} \end{bmatrix} \begin{bmatrix} \Delta \mathbf{u} \\ \Delta p \end{bmatrix} = \begin{bmatrix} \mathbf{s}_{nod} \\ \mathbf{0} \end{bmatrix} - \begin{bmatrix} \mathbf{s}_{sig} + \mathbf{s}_{acc} \\ \mathbf{s}_{ine} \end{bmatrix} \quad (87)$$

$$\mathbf{m} \Delta \dot{\mathbf{T}} + (\mathbf{k}_{con} + \mathbf{k}_{dif}) \Delta \mathbf{T} = \mathbf{S}_{nod} - \mathbf{m} \dot{\mathbf{T}} - (\mathbf{k}_{con} + \mathbf{k}_{dif}) \mathbf{T} + \mathbf{S}_{heat} \quad (88)$$

The different $\mathbf{k}$ s represent "stiffness" matrices and the $\mathbf{S}$ s are the "loads". In the energy Eq. 88 the temperature state of the last time step as well as the dissipative heat will be the loads. Besides the traditional loads on the nodes, the acceleration term will be regarded as a load in the mechanical Eq. 87.

A number codes, which can be utilized in the study of extrusion, has been developed. Some of these programs are made with somewhat more general perspectives, but function quite well in the study of extrusion although they are not ideally suited. One such is the program FIDAP, which is addressing more general fluid mechanical problems with an Eulerian perspective, and others are programs such as Forge2, Autoforge and Deform, which are Lagrangian programs meant to handle various problems in the field of materials forming. The main weakness of all these codes is that they originally were not meant to handle

the special geometry of the extrusion process. Problems arise when material is entering the bearing channel and undergoes extreme deformation. In Lagrangian programs elements are severely deformed and will not yield proper results unless remeshing is performed continuously. In Eulerian codes a constant velocity at the outlet can not be specified, and therefore one will not be able to simulate the self-stabilizing effect which usually takes place in the bearing channel. Special programs, which handle most case-sensitive aspects, have been developed. One such is ALMA2 π , which has been developed at SINTEF/Norwegian University of Science and Technology supported by Hydro Aluminium.

Experiments performed with the split-billet technique indicate that material deformation during extrusion is localized to very narrow shear zones as the one extending from the outlet of the container towards and along the container wall. This is typical for plastic deformation as the underlying equations in the case of constant yield shear strength will be hyperbolic and in fact allow distinct velocity discontinuities. Infinitely large spatial changes in velocity can, however, not be found for results provided by FEM, as the underlying equations are no longer hyperbolic, and as the solution itself is not given as a continuous function in space. A perfectly plastic material behavior for the whole billet is in fact impossible to simulate with methods known today, as the stiffness matrix will be singular and the velocity field indeterminate. Furthermore, if the material shows very low strain rate hardening, calculation times tend to be very long because a great number of iterations are needed to determine the states of deformation and stress. If sufficiently small elements are applied and the strain and strain-rate hardening exponents in a Norton-Hoff relation are taken to be sufficiently low, however, results in satisfactory accordance with as well analytical as experimental result can be obtained. Figure 48 provides a comparison of a deformed network found experimentally and numerically. When studying the figure, one should remember that flow in the container is more easily simulated than that in the bearing channel, and that numerical results need not be that satisfactory in regions with large strain rates.

RESEARCH TOPICS

The use of aluminum sections in buildings, architecture, furniture, transport, electronic equipment, heat exchangers, and in mechanical design generally, is well established. The thin-walled complex, multifunctional shape, with its low cost dies, with its availability, flexibility in shape, ease of fabrication and attractive surface, has made it a favorite for the creative designer. Many successful products have been created. Still there are considerable innovative potentials in exploiting the extrusion technology, its downstream processes and the aluminum alloys. Particular challenges are within the following areas:

Fig. 48 Comparison of numerically calculated (a) and experimentally found flow field; (b) for a reduction ratio of about 6 and under the assumption of full sticking at walls

- Reducing the variability of dimensions, shape, properties and surface appearances without cost increase.
- Reducing wall thickness with narrow tolerances and increasing the strength of a section at reduced cost.
- Combining generally available sections to large sections by stir welding, instead of using large presses for large sections with limited availability and high cost.
- Combining extrusion, bending and hydroforming for cost-effective production of complex three-dimensional shapes with narrow tolerances and properties.

As will and has been shown in this chapter, the hot extrusion process is characterized by:

- A strong interaction between mechanical, thermal and metallurgical parameters during a press cycle.
- A continuous and transient variation of temperature distribution and metal flow field in container and die during the press cycle. Each material element goes through a different thermo-mechanical history.
- Sharp gradients in strain rate and temperature, both spatial and temporal, when the deforming material flows into and through the bearing channel.
- An interaction between the displacements of the bearing channel walls, bearing channel friction, formation of the section surface and the stability of flow.
- An absence of adequate in line sensors, predictors and actuators for controlling the variations in dimensions and shape of the extruded sections.
- An absence of analytical models of the extrusion process being able to “catch” the basic feature of thin walled extrusion; the self-stabilization of the process.
- An absence of 3D numerical codes that are at a stage of development where studies of the self-stabilization phenomenon can be studied.

Some selected research topics will be discussed that now seems ripe for “attack”. These topics are considered

as fundamental, pre-competitive problems, that will form the base for the scientific theory of thin-walled extrusion. According to Støren,^[72] by the theory of extrusion we understand a theory that is able to make predictions about:

- The flow pattern, the distribution of temperature and stresses and the evolution of microstructure of the deforming material in the container and the through the whole process.
- The properties of the extruded, heat treated and fabricated section as function of chemical composition, initial microstructure, shape of the section and the parameters of the processes that the section passes through from raw material to finished product.
- The sensitivity to variations in the die and section design and processing history on the material properties, surface, dimensional tolerances and optimal processing speed with a specified shape, alloy and production set up.

As pointed out by Bishop^[73] already in 1957 one has to apply the continuum thermo-mechanics of extrusion to quantify phenomena that are primarily of metallurgical origin, such as speed limit phenomena, flow resistance, the evolution of microstructure and the properties of the extruded section. A fully coupled theory of mechanical, thermal and metallurgical parameters has therefore to be developed. This, then may give the basis for the synthesis of alloy development, process-innovation and production optimization that is needed to release the potential of extrusion-based components and products with respect to the improvements in quality properties, economic efficiency and ecological effectiveness (Figs. 14 and 15). In the following, a possible “research strategy” to achieve this is outlined.

Numerical 3D Simulation and Laboratory Extrusion Experiment Validation

The development of software for 3D thermo-elasto-viscoplastic flow of metals in interaction with thermo-elastic deflections of the tooling and the die is now approaching a level of precision and speed that the basic problem of the thin-walled extrusion process can be attacked,^[74] namely the phenomena of self-stabilization. With self-stabilization one understands the ability of the process to react to variations in the flow-, temperature- and the flowstress-field of the material approaching the bearing channel in such a way that the variation in dimension, shape, microstructure and surface-properties are kept within the required limits during a press cycle. In order to study this basic phenomenon in a systematic and quantitative way, the following set of systematic experiments is proposed performed (Fig. 49):

- Thin strip extrusion.
- Thin-walled tube extrusion.
- Rectangular hollow thin walled section.

Fig. 49 Generic sections for 3D modeling

For the thin strip the width is kept constant, whereas the thickness is gradually reduced, giving an increase in reduction ratio, until instability in the form of buckling of the section is reached. In the tube, the reduction ratio is kept constant, whereas the tube diameter is increased and the wall thickness is decreased until the limit of satisfactory extruded section is reached. In the rectangular hollow section, the cross sectional area of the mandrel and the thickness of the section are kept constant, whereas the width/height-ratio is increased until the limit of satisfactory extruded section is reached. In the numerical simulation of these processes one will see that bearing channel phenomena will have major influence of the simulation results.

Die Deflections, Friction and Surface Formation in the Bearing Channel

A proper understanding of the interaction between the aluminum and the bearing surfaces has been viewed as a key to controlling dimensional variability and surface quality of the extruded profiles, and intensive research has over the last few years been undertaken in this field.^[75] Most of the interest has been connected to the study of choked dies as only these are of commercial interest. If the die is designed with a release, friction forces will naturally be lower. However, the surface quality will usually be unsatisfactory since tearing, die lines or streaking may be caused by pick up deposited directly behind the main area of contact between die and the extruded metal.

Due to the existence of friction forces and a non-linear material model, the flow through the bearing channel is a plug flow driven by the change in pressure from the inlet to the outlet. However, since the bearings are relatively

narrow, a steady state can hardly be obtained. As a result, the velocity profile may be expected to change almost continuously through the bearing channel. In the inlet, velocity components normal to the bearings will exist as the material flow enters the channel from the container. At the outlet the velocity field ought to be uniform.

Figure 50 shows some of the phenomena observed in an experimental set up of extrusion of a thin strip with a split die, advised by Abtahi^[76–78] and further studied by Tverlid^[79] and Aukrust et al.^[80] In the inlet to the bearing channel, the flowing material is sticking to the die due to high contact pressures. By this one understands that there will be no relative velocity between particles on the boundary between the metal and the tool and, therefore, no distinct surface of the extruded metal either. The shear stress will be given by the constitutive equation of the deforming metal and may be relatively high due to high strain rates, 1000 to 10,000 [1/sec]. As the pressure normal to the bearing surface decreases towards the outlet, however, one is to expect that the sticking friction at a certain point, the slip point, must be replaced by sliding. The sliding friction is regarded to be of Coulomb type since there only will be partial contact between deforming material and the bearings and the magnitude of shear stress is found to be dependent on the pressure normal to the bearing surface. Over a relative short distance denoted the transition region the slipping speed is increased from zero to full outlet extrusion speed. A positive gradient in the slipping speed means that new surface is forming. In the same region material particles will also move in a direction normal to the bearings. The position of the slip point will be determined partly by the normal stresses in the end of the bearing channel, the angle of choke, which affects the pressure build-up, and the inlet radius to the bearing channel. Only

Fig. 50 Bearing channel friction and stability of flow

in the limiting case of very large angles should one expect the slip point to be close to the outlet.

The surface structure and topology of an extruded section is created and modified in the transition and slipping regions. Furthermore, the presence of a layer of oxidized metal is thought to be importance to both the friction conditions and surface generation. While such a layer is broken up and removed from the sticking region of the bearing surfaces, it remains attached to the bearings and simplifies gliding in the region of slipping. In the case of extrusion with the 6XXX-series of alloys, it has been found that micro die lines present on the profile surface can be related to hard particles existing in the adhesive layer of the slipping region. The regions of slip and stick may easily be identified on the bearings of a die after extrusion as a relatively thick adhesive or oxidized layer is a witness of the presence of the former. Between the areas of slipping and sticking, a transition region of a certain length is also found to exist.

During the press cycle, the forces on the die and the temperature distribution in the die, will vary, giving variations in die deflections. This then, dependent on the tooling and die design, may cause variations in the choke angle and the bearing channel opening during a press cycle. These parameters, the normal stress at the outlet, and the deflection of

the bearing surfaces of the die, influence the friction and the local reduction ratio, and thus the pressure build up in the bearing channel. Physical understanding and quantification of these effects, constitute a major scientific challenge to the study of thin walled, dry friction, hot extrusion of aluminum.

The Stability of Flow

When the material in some parts of a thin section tends to flow faster than the rest of the section, compressive stresses is set up in those parts and tensile stresses in others (Fig. 50). The variations in normal stresses over the cross section of the extruded profile leaving the bearing channel, will influence the position of the slip point. Under the influence of compressive stresses the slip point moves towards the outlet, and a higher friction and thus also a higher pressure build-up in the bearing channel is experienced. Tensile stresses have the opposite effect. The slip point is moved away from the outlet, and friction is reduced in the bearing channel, causing a reduced pressure build up in the inlet. This conclusion can be drawn directly from the simple slab analysis in the previous chapter. The change in pressure distribution, depending of the material response to stress variations, will promote a more balanced outlet flow.

If the change in outlet normal stress distribution causes buckling in the compressive region or thinning and even cracking in the tensile stress region, or if the pressure build-up in the inlet to the bearing channel cause redistribution of loads on the die that give die defections that acts against the self-stabilization effect or gives unacceptable variations in section thickness, then the limits of extrudability is reached.

From this description it is clear that a detailed thermo-mechanical quantitative model of these effects is critical if a successful 3D-computer codes describing the extrusion process are to be developed. Detailed physical models of material response, of the conditions in the bearing channel, of surface formation and of stick-slip mechanisms cover several levels of magnitude, from atomistic to continuum level.

Alloy Development, Process Innovations and the Limits of Extrudability

Based on the progress of 3D-simulation and experimental validation of flow in thin-walled extrusion, combined with the

- Computation of the tool and die deflection.
- Detailed quantitative description of the response of the alloy with respect to microstructural evolution and flow resistance.
- Understanding and modeling of the bearing channel friction and surface formation phenomena.
- Prediction of the limits of self-stabilization of flow.

the limits of extrudability can be studied in a systematic and quantitative way. Combined with the knowledge and creativity of the experienced extrusion metallurgist, production and die experts as well as the product designers, this new scientific based knowledge of extrusion will give way to alloy systems based on recycled aluminum, new innovative principles of die, tooling and press design, section handling and down stream processes with quality properties, economic efficiency and ecological effectiveness that mark the sustainable products of tomorrow.

Abstract

This article deals with torsion fatigue tests carried out on the aluminum alloys: AISI 6061-T6 and 6063-T5, under two load ratios: $R = -1$ and $R = 0$, both of them at 10 Hz of frequency. The tests were obtained at room temperature (23°C) and with environmental humidity comprised between 35% and 45%. Results reveal a noticeable fatigue endurance reduction on tests with $R = 0$ against tests at $R = -1$ for both aluminum alloys. The load ratio was fixed by imposing the initial angle before the testing starting. A new torsion fatigue machine has been developed by two of the authors (under patent consideration before the Mexican Institute of Industrial Property), which has the versatility of torsion tests at different frequencies and load ratios; a general description of this machine is presented in the article. The torsion fatigue life and the fracture surfaces were analyzed for the two aluminum alloys and both torsion fatigue load ratios, leading to drawing up the conclusions related to this research article.

Keywords: Aluminum alloys; Comparative study; Crack initiation and propagation; Load ratio; Torsion fatigue testing.

INTRODUCTION

The aluminum alloys AISI 6061-T6 and 6063-T5 are two of the most popular aluminum alloys used in industrial applications. Concerning the 6061-T6 alloy, this material presents a good balance between weight, price, and mechanical properties, allowing wide industrial applications such as truck and trailer flooring, construction of aircraft structures, pneumatic installations, ladders, cycle frames, boats, and watercraft.^[1–3] The alloy 6063-T5 presents lower mechanical properties compared to 6061-T6; nevertheless, a considerably higher corrosion resistance and weldability combined with better fatigue resistance under tension-compression, which leads to wide industrial applications, including pipe and tube for irrigation systems, door and window frames, electrical components and conduits, railings and furniture, heat sinks, antenna towers, aircraft structures, bridges, car industry, structures used with extremely low temperatures, etc.^[4–6] These two aluminum alloys are subjected to oscillating mechanical loading (fatigue), under use conditions; furthermore, some mechanical tests have been carried out in order to assess the mechanical response under

loading: tension–compression,^[7,8] small punch testing,^[9] microstructural features related to surface appearance and mechanical properties,^[10] and hardness tests and precipitation hardening.^[11] Concerning torsion fatigue testing on these aluminum alloys, some efforts have been oriented to predict the torsional fatigue life and remaining life based on the total strain energy dissipation during a monotonic fracture and cyclic processes,^[12] the confrontation between rotating bending fatigue and torsion fatigue,^[13] or investigating the effect of load ratio R on torsion tests.^[14] Nevertheless, torsion fatigue investigations on aluminum alloys are not widely available today; some experimental results have been reported in the past years, such as ultrasonic torsion fatigue testing on the 2024-T351 aeronautical aluminum alloy under constant vibration amplitude^[15] and the effect of mean shear stress on torsion fatigue failure of 2A12-T4 aluminum alloy under constant amplitude of loading.^[16] For these two references, even if the heat treatment has not been the same for the 2024 aluminum alloy, the torsion fatigue endurance seems attains the 5×10^5 cycles when the shear stress amplitude is close the 180 MPa, considering null mean shear stress $\tau_m = 0$ ($R = -1$). Concerning the

aeronautical aluminum alloy 7075-T651, under torsion testing with zero mean shear stress ($\tau_m = 0$), it has been reported 150 MPa of stress amplitude under torsion fatigue, allowing the half million of cycles of fatigue life.^[17] The aeronautical aluminum alloys are subjected to environmental corrosion, particularly the exfoliation corrosion, which is a drastic intergranular corrosion phenomenon influencing the fatigue endurance. Recent fatigue investigations on the 2024-T3 alloy with load ratio $R = 0.1$ and frequency of 1 Hz show that fatigue life may be estimated by the stress concentration factors related to corrosion and the sample shape.^[18]

Aluminum alloys series 7000 and 2000 present higher content of magnesium compared to the 6000 series; this alloying element provides higher strength. Despite this fact, some applications of the 6000 series have been developed for the aeronautical–aerospace industry, including wings and fuselages for the homebuilt aircrafts (reduced use on commercial or military aircraft), helicopter rotor components, missiles and space, etc.^[19,20]

This article presents a study of two aluminum alloys that are undergoing torsion fatigue under the loading rates $R = -1$ and $R = 0$, with the aim to investigate the comparative behavior of these aluminum alloys under the two described torsion load ratios. The torsion fatigue tests for all specimens were carried out under controlled constant torsion amplitude.

TESTING MACHINE, MATERIALS, AND TESTING CONDITIONS

TESTING MACHINE

All experimental tests have been carried out on a new torsion fatigue machine developed in our laboratory,^[21] which is in process of patent demand. Concerning the testing specimen, noninternational standardization is available for torsion fatigue specimens; the norm ASTM A938-97 is related to torsion tests of a uniform section wire. The dimensions (mm) of testing specimen, shown in Fig. 1a, were determined to induce a shear stress at the neck section of specimen, below the corresponding shear strength

of these two aluminum alloys (207 MPa for the 6061-T6 alloy and 117 MPa for the 6063-T5 alloy).

A general description of the testing machine is as follows: the rotating motion is communicated to vertical rotating axis by a mechanical system of chain and gear; the power is provided by a servomotor which is controlled through a software program developed in the “Robotics” platform, allowing communicating rotating motion with $\pm 0.09^\circ$ of precision. The vertical axis receives the torsion displacement by the chain and gear and communicates it to the upper free torsion chuck and the specimen, as shown in Fig. 1b. The automatic stop and the automatic recording of cycles are carried out by electric current continuity: the servomotor and the electronic counter are controlled by electric current through the testing specimen; when torsion failure occurs, the current is interrupted leading to stop the servomotor and the counter.

MATERIALS

Commercial grades 6061-T6 and 6063-T5 of aluminum alloys were selected for this investigation; the chemical composition in weight (%) and the principal mechanical properties for such materials are described in Tables 1–4, respectively.

TESTING CONDITIONS

The experimental tests were obtained at room temperature and with environmental humidity between 35% and 45%. The two aluminum alloys were subjected to constant displacement fatigue tests at four levels of applied load induced by a fixed torsion angle of: 2.43° , 2.16° , 1.89° , and 1.62° , which corresponds to 50.9%, 45.2%, 39.6%, and 34% the shear strength of 6061-T6 alloy (207 MPa), and 90%, 80%, 70%, and 60% the shear strength for the 6063-T5 aluminum alloy (117 MPa). Since, the shear modulus for the two alloys are very close (Tables 2 and 4), a torsion displacement induces similar shear stress for the two alloys at the neck section; nevertheless, this shear stress represents a different percentage in regard to the corresponding shear

Fig. 1 (a) Dimensions (mm) of torsion testing specimen and (b) principal components of the torsion fatigue machine

Table 1 Chemical composition in weight (%) for the 6061-T6 aluminum alloy

Cr	0.04–0.35	Mn	Max. 0.15	Ti	Max. 0.15
Cu	0.15–0.4	Other, each	Max. 0.05	Zn	Max. 0.25
Fe	Max. 0.7	Other, total	Max. 0.15		

Table 2 Principal mechanical properties of the 6061-T6 aluminum alloy

Shear strength (MPa)	Ultimate tensile strength (MPa)	Elongation (%)	Shear modulus (GPa)	Hardness (Brinell)
207	310	0.33	26	95

Table 3 Chemical composition in weight (%) for the 6063-T5 aluminum alloy

Si	Fe	Cu	Mn	Mg	Cr	Zn	Ti	Al
0.3–0.6	0.35	0.1	0.1	0.4–0.85	0.1	0.1	0.1	>96.9

strength for the two aluminum alloys. The 90% of the shear strength is obtained for the 6063-T5 alloy when applying a torsion angle of 2.43° (higher shear stress at the neck section close to 105 MPa). Under controlled displacement fatigue tests, the stiffness of material decreases at the end of test; it was observed that stiffness was maintained quasi constant over the 95% of the total testing time; the crack initiation consumes close to 95% of the total testing time and the remaining 5% the crack propagation, approximately.

The full reverse load ratio $R = -1$ was implemented by applying a starting torsion angle in the contraclockwise direction and then, oscillating from this position to a maximum angle in the opposite direction as shown in Fig. 2a. The load ratio $R = 0$ was carried out from a nonstressed initial position 0° to attain the maximum stress with displacements according to the clockwise direction (Fig. 2b). All testing specimens were machined following a similar process in order to avoid important variation on the surface roughness; Fig. 3a shows a set of machined specimens for which the arithmetic average of absolute values of the roughness profile ordinates R_a was close to $8 \mu\text{m}$. Even if the surface roughness and the related geometric parameters are not able to correctly describe the effect of roughness on the fatigue life of metallic alloys,^[22,23] the stress concentration factor K_t related to the surface machining roughness was obtained in this study for the torsion fatigue tests: K_t surface = 1.18. The stress concentration factor for the sample shape was investigated by finite element method, as shown in Fig. 3b; the value obtained has been the shear

stress at the neck section of specimen ≈ 46 MPa, divided by the shear stress at the joint point between constant and variable surface section of test specimen 9.5 MPa, that is, K_t shape = $46/9.5 = 4.84$. Concerning the test frequency, all tests were performed at 10 Hz.

EXPERIMENTAL RESULTS

Numerical simulations were carried out in order to determine the rotating displacements along the testing specimens and the induced shear stress that is concentrated at the neck section, as shown on Fig. 4a and b, respectively. The numerical simulation was obtained in the Ansys Multiphysics software, and the profile of torsion specimens was determined in order to induce a high stress at the neck section of the hourglass shape specimen. The results shown in Fig. 4b illustrate the case for a torsion rotation of 1° at the upper constant section of the aluminum alloys, whereas the opposite side was clamped. The highest shear stress on Fig. 4b corresponds to the simulation for the 6061-T6 alloy: $207 (0.34)/1.62 = 43.4$ MPa and for the 6063-T5 alloy: $117 (0.6)/1.62 = 43.3$ MPa. A similar high shear stress for 1° of torsion in both aluminum alloys is obtained, since taking the reference of 1.62° of torsion, this represents the 34% of the shear strength for the 6061-T6 alloy (207 MPa) and the 60% for the 6063-T5 alloy (117 MPa).

TORSION FATIGUE RESULTS FOR THE 6061-T6 ALLOY

The torsion fatigue endurance for the 6061-T6 aluminum alloy is shown in Fig. 5. The results for two load ratios ($R = -1$ and $R = 0$) are plotted, revealing an

Table 4 Principal mechanical properties of the 6063-T5 aluminum alloy

Fig. 3 (a) Set of torsion testing specimens machined from a solid bar and (b) shear stress (Pa) obtained along the specimen with a torsion angle of 1° , applied at the beginning of the variable section

Fig. 4 (a) Torsion displacements along the specimen (m), under 1° of torsion at the upper side and (b) shear stress distribution in Pa along the specimen for the same applied torsion load

important decrease in fatigue life for loading rate $R = 0$ compared to $R = -1$, particularly for the low applied loads. For example, with a torsion angle of 1.9° (≈ 82 MPa), fatigue life under $R = 0$ is close to 50,000 cycles, whereas

Fig. 5 Fatigue endurance with load ratios $R = 0$ and $R = -1$ for the 6061-T6 aluminum alloy

with load ratio $R = -1$ fatigue life attains near 300,000 cycles. Concerning the high applied load or low number of cycles, no difference is observed for fatigue behavior on this aluminum alloy under torsion loading: torsion angle between 2.43° and 2.16° , corresponding to 105.5 and 93.7 MPa, respectively, of shear stress. Logarithmic regression lines have been obtained from the experimental points plotted in Fig. 5; no measure of dispersion

Fig. 6 Fatigue endurance with load ratios $R = 0$ and $R = -1$ for the 6063-T5 aluminum alloy

level of the experimental points was obtained in applying the logarithmic regression. The corresponding linear equations are

$$D = -0.3308 N + 3.6732 \quad (1)$$

and

$$D = -0.6377 N + 4.901 \quad (2)$$

for $R = -1$ and $R = 0$, respectively. In these last equations, D is the degree of torsion in the vertical axis of Fig. 5, and N is the logarithm base 10 of the number of cycles, represented on the horizontal axis.

TORSION FATIGUE RESULTS FOR THE 6063-T5 ALLOY

Fatigue endurance for the 6063-T5 aluminum alloy is shown in Fig. 6. A similar behavior is observed compared to the previous alloy; nevertheless, some general particularities are related to this material: (a) the difference on fatigue endurance between $R = -1$ and $R = 0$ is less sharply when the applied load is modified. For example, fatigue endurance with 1.9° of torsion (~ 82 MPa) is close to 30,000 cycles when $R = 0$; whereas this value reaches 100,000 of cycles when $R = -1$ and (b) in the zone of short fatigue life, less than 10,000 cycles, the fatigue endurance for $R = -1$ continues to be highest compared to $R = 0$, even if the corresponding difference decreases.

For this aluminum alloy, the corresponding linear equations are

$$D = -0.3934 N + 3.8672 \quad (3)$$

and

$$D = -0.4533 N + 3.9464 \quad (4)$$

for $R = -1$ and $R = 0$, respectively. The description of D and N parameters is similar to Eqs. 1 and 2 of the previous aluminum alloy. For the high loading on this alloy, which corresponds to 105 MPa (90% of the shear strength), local plastic deformation and local yielding is observed, as shown in Fig. 8c.

DISCUSSION

The stress amplitude to attain half million of cycles of torsion fatigue life under loading rate $R = -1$ for the mentioned aeronautical-aerospace aluminum alloys is revealed as follows: the alloy 2024 attains this number of cycles with 180 MPa of stress amplitude, close to 150 MPa is the stress amplitude required for the 7075 alloy; whereas these values were 76 MPa for the 6061-T6 alloy and 69 MPa for the 6063-T5 alloy. The stiffness of the testing aluminum alloys was maintained quasi constant for approximately 95% of the testing time, implying that crack initiation consumes the large portion of testing time.

Fracture surfaces were observed by SEM as shown in Figs. 7 and 8 for the 6061-T6 and 6063-T5 alloys, respectively. Concerning the 6061-T6 aluminum alloy, Fig. 7a shows the fracture surface and different crack initiation sites that are associated with crack propagation in radial direction from the exterior surface to the center of fracture surface. This tendency on crack propagation is typical in torsion fatigue for an aluminum alloy,^[24] the crack initiates at the exterior surface where the largest shear stress amplitude is applied; then, when this loading overcomes a threshold value, depending on the nature of material, the amplitude of load, and the number of cycles of loading, crack propagation takes place in radial direction, as shown in Fig. 7a. Ductile fracture is observed in this alloy; it is related to plastic deformation and micro-voids coalescence at the interior zone of fracture surface, as depicted on Fig. 7c. In addition, intergranular crack propagation takes place following a radial direction, located inside the granular zone, as it is observed in Fig. 7b.

The fracture images for the aluminum alloy 6063-T5 are presented in Fig. 8. A principal crack initiation site is distinguished on fracture surface, Fig. 8a, which initiates at the exterior surface and is associated with the highest plastic deformation, as shown in Fig. 8c. Intergranular crack propagation is observed again following a radial direction, as shown in Fig. 8b. The 6063-T5 aluminum alloy presents higher ductility compared to 6061-T6; this may be at the origin of only one appreciable crack initiation site. For the alloy 6061-T6, a competition of different crack initiation sites seems to be observed.

The torsion loading induces plastic deformation non-uniform along the radial direction of fracture surfaces; it follows that significant hardening enhancements can be

Fig. 7 Fracture surface for aluminum alloy 6061-T6: (a) radial fatigue crack propagation induced by cyclic torsion, (b) intergranular crack propagation converging to the granular zone, and (c) micro-voids coalescence generated by torsion loading

Fig. 8 Fracture surface for aluminum alloy 6063-T5: (a) radial fatigue crack propagation induced by cyclic torsion, (b) intergranular crack propagation converging to the granular zone, (c) micro-voids coalescence and local plastic deformation generated by torsion loading: 105 MPa of shear load

present at the micron scale.^[25–27] Furthermore, the sizes of micro-voids increase with ductility, leading to facilitate the coalescence of micro-voids and reducing the crack propagation paths, under stress triaxial loading.^[28]

CONCLUSIONS

The following conclusions can be listed from the present study:

- Experimental torsion fatigue results were obtained for the two aluminum alloys: 6061-T6 and 6063-T5, under two load ratios: $R = 0$ and $R = -1$.
- The torsion fatigue endurance decreases for the load ratio $R = 0$, compared to $R = -1$, for the two aluminum alloys.
- The torsion fatigue endurance of the 6061-T6 alloy is close to 5×10^4 cycles when the amplitude of shear stress is near the 82 MPa (the 39.6% of shear strength of this material) and $R = 0$; whereas fatigue endurance

increases to 3×10^5 cycles for the same material and same amplitude of shear stress with $R = -1$. For the 6063-T5 alloy, the fatigue endurance attains the 3×10^4 cycles when the amplitude of shear stress is 82 MPa approximately (the 70% of shear strength of this material) and $R = 0$; this value is 1×10^5 cycles when $R = -1$ for the same amplitude of shear stress.

- Under the same amplitude of shear stress and same load ratio, the aluminum alloy 6061-T6 shows highest torsion fatigue endurance compared to 6063-T5. This is related to the higher shear strength of 6061-T6 compared to the 6063-T5, even if the last alloy presents higher ductility and higher capacity to absorb strain energy by plastic deformation.
- The equations for the four logarithmic regression lines have been obtained concerning the two aluminum alloys and the two load ratios. In these equations, the angle of torsion and the amplitude of shear stress with the logarithm base 10 of the number of torsion fatigue cycles are related.
- The crack initiates at the exterior surface of specimen under torsion fatigue testing, where the largest shear stress amplitude is induced; then, it propagates to the fracture surface center in a radial direction.
- Two or more crack initiation sites were observed on the fracture surface of 6061-T6 alloy, whereas for the 6063-T5 alloy, only one crack initiation site was frequently detected.
- The sizes of micro-voids increase with ductility; highest sizes of micro-voids facilitate their coalescence and tend to reduce the number of crack initiation sites.
- Further investigations will be undertaken in the next future to improve the understanding of torsion fatigue endurance on these aluminum alloys, particularly the hardening effect related to fatigue testing frequency, the shape and coalescence of micro-voids under torsion loading, the stress concentration factors associated with the torsion fatigue life, etc.

Institute of Materials Engineering, Faculty of Mechanical Engineering, University of Kassel, 34109 Kassel, Germany

Abstract

Today, aluminum alloys are being considered as substitutes for many automotive parts made from steels because of the growing interest in producing lightweight vehicles. Consequently, it is crucial to understand the fatigue lifetime—the property itself and its behavior—of aluminum alloys, and to clarify its capacities at both room temperature and elevated temperatures. In particular, the aluminum alloys in the AA5xxx (non-precipitation-hardenable) and AA6xxx (precipitation-hardenable) series are very similar to those found in automotive industries, and are both frequently mentioned and the focus of studies. The satisfactory fatigue lifetime and the improved strength of aluminum alloys make them a strong candidate for automotive industries. This article focuses upon the fatigue property and behavior of aluminum alloys at room temperature and elevated temperatures. Then, the focus will shift to the concept of mechanical surface treatment, the so-called deep-rolling process, which can be used to improve the fatigue lifetime of aluminum alloys. The effects of a mechanical surface treatment on the fatigue properties and behavior of the aluminum alloys AA5083 and AA6110, and the residual stress stability at room temperature and elevated temperatures has been discussed. Moreover, modified deep-rolling processes, i.e., deep-rolling followed by an appropriate annealing process and high-temperature deep-rolling, have been elaborated upon in this article.

Keywords: Deep-rolling; Fatigue; Mechanical surface treatment; Residual stress.

INTRODUCTION

In the last few decades, a growing amount of research has focused upon steels and how to improve their strength while maintaining a sufficient level of formability. This pertains to high-strength steels or advanced high-strength steels. If higher mechanical properties can be created in steels, products with smaller sizes and lower weights can be achieved. Light metals, e.g., aluminum, magnesium, and titanium alloys, represent real, potential candidates that can substitute steels in various industries owing to many of their advantages, i.e., corrosion resistance, good formability, and recycling potential.^[1–6] This applies to aluminum alloys from the AA5xxx and AA6xxx series, which are serious contenders for the automotive industry. Many automotive parts that were made of steels in the past have now been converted to aluminum alloys. Consequently, the mechanical properties of aluminum alloys from the AA5xxx and AA6xxx series are very important, particularly the fatigue property and behavior. Many automotive parts made from aluminum alloys are subject to elevated temperature conditions. For this reason, we investigated the fatigue properties at room temperature and elevated temperatures. Mechanical

surface treatments, e.g., shot peening, deep-rolling, or laser shock peening, are methods used to enhance the fatigue properties of metallic materials. Macroscopic, compressive residual stresses induced near the surface and work hardening states serve to inhibit or retard crack initiation and growth.^[7–9] Thus, stable residual stresses and work hardening states on the surface and in regions near the surface are very important to preserve the benefits of mechanical surface treatments, especially under high loading and/or at elevated temperatures, whereas the residual stresses and work hardening states can be relaxed. The relaxation of residual stresses and work hardening states correlates with a dislocation movement, a rearrangement, and an annihilation in the recovery mechanism. The strain aging concept, which is based on the obstruction of dislocations by solute atoms is introduced to stabilize the induced compressive residual stresses and work hardening states. Regarding this aspect, the strain aging concept was recently integrated into mechanical surface treatments, i.e., mechanical surface treatment followed by annealing^[10–15] or high-temperature mechanical surface treatment.^[16–21] In this article, the fatigue lifetime of aluminum alloys AA5083 and AA6110 is examined in non- and deep-rolled conditions at room and

elevated temperatures. The residual stress and work hardening state stabilities are discussed. Finally, the results of modified deep-rolling processes performed on as-quenched aluminum alloy AA6110 and the effects on the fatigue lifetimes are presented.

FATIGUE OF ALUMINUM ALLOYS

The fatigue and cyclic deformation behavior of aluminum alloys strongly depend on dislocation movements and interactions, i.e., dislocation–dislocation or dislocation–precipitate interactions. In the case of non-heat-treatable aluminum alloys, e.g., AA5083, dislocations can easily move through solute atoms since there are no effective obstacles. Thus, dislocation–dislocation interactions as well as work hardening took place as a consequence of a cyclic hardening behavior at room temperature and elevated temperatures. Figure 1 shows cyclic deformation curves recorded during stress-controlled, push–pull fatigue tests performed at room temperature and elevated temperatures ranging up to 250°C. In the case of heat-treatable aluminum alloys, e.g., AA6110, the cyclic deformation behavior is governed by the size and structure of the precipitates embedded within the aluminum matrix. If precipitates are very small, such as in the under-aged aluminum alloy AA6110, which was aged at a temperature of 160°C for about 1 h, dislocations can move and cut precipitates easily. Thus, cyclic hardening behavior was observed at room temperature and elevated temperatures ranging up to 200°C. It indicates that the heat during fatigue tests performed at 200°C is not sufficient to effectively develop Mg_2Si (β'')-precipitates, in the under-aged aluminum alloy AA6110. However, at a test temperature of 250°C, cyclic softening curves were observed as shown in Fig. 2. This means that for this

Fig. 1 Cyclic deformation curves of aluminum alloy AA5083 at room temperature and elevated temperatures up to 250°C

Fig. 2 Cyclic deformation curves of the under-aged aluminum alloy AA6110 at 250°C

temperature precipitates could effectively be produced, which gives rise to a precipitation strengthening mechanism before the fatigue tests (10-min waiting period before fatigue test). The to-and-fro motion of dislocations during cyclic deformation through the ordered precipitates causes local mechanical disordering of the atoms in the precipitates. The structure of the precipitates becomes disordered and degrades. The hardening effect is lost, and, therefore, cyclic softening is observed.^[23–24] This phenomenon is comparable to the peak-aged aluminum alloy AA6110, which was aged at 160°C for about 12 h, producing precipitates which are effective in size and structure. Consequently, cyclic softening behavior was detected for the peak-aged aluminum alloy AA6110 at room temperature and elevated temperatures. Higher stress amplitudes and temperatures led to higher plastic strain amplitudes as a consequence of lower fatigue lifetimes of aluminum alloys (see Fig. 2). Here, the Coffin–Manson equation, which also applies for other metallic materials, was taken into account.^[24–25] The s – N curves of aluminum alloys AA5083 and peak-aged AA6110 at room temperature are depicted in Fig. 3. At elevated temperatures, higher plastic strain amplitudes were detected as a consequence of lower fatigue lifetimes (see Figs. 1 and 3).

FATIGUE OF MECHANICALLY SURFACE-TREATED ALUMINUM ALLOYS

A mechanical surface treatment, the so-called deep-rolling process, was performed on the aluminum alloys AA5083 and AA6110. The deep-rolling process was performed at room temperature using a hydraulic rolling device with a 6.6-mm spherical rolling element and a pressure of 100 bar. Generated residual stresses and work hardening states at the surface and in regions near the surface of the

Fig. 3 The s - N curves of aluminum alloy AA5083 and peak-aged aluminum alloy AA6110 at room temperature and at 250°C

deep-rolled alloys benefit fatigue lifetime enhancement, because they inhibit or retard crack initiation as well as crack growth.^[7-9] The depth profiles of compressive residual stresses and work hardening states (represented by the full width at half maximum (FWHM)) of the deep-rolled, peak-aged aluminum alloy AA6110 were measured using X-ray diffraction (XRD), as shown in Fig. 4. The deep-rolled aluminum alloys AA5083 and AA6110 were cyclically deformed at room temperature and elevated temperatures. The shape of the cyclic deformation curve of the deep-rolled alloys normally should not be disturbed by induced compressive residual stresses and work hardening states. Deep-rolled aluminum alloys commonly displayed lower plastic strain amplitudes during fatigue tests performed at room temperature and elevated temperatures in high-cycle fatigue regimes compared to the non-deep-rolled aluminum alloy. However, in low-cycle

Fig. 4 The depth profiles of residual stresses and FWHM values of the peak-aged aluminum alloy AA6110

fatigue regimes, higher plastic strain amplitudes were detected for the deep-rolled aluminum alloy at room temperature and elevated temperatures, as shown in Fig. 5. Consequently, lower fatigue lifetimes of the deep-rolled alloy were measured. Figure 6 shows s - N curves of the peak-aged aluminum alloy AA6110 both in non- and deep-rolled conditions. The effectiveness and ineffectiveness of the deep-rolling process can be analyzed using the intersection points in the s - N curves in Fig. 6. Therefore, all intersection points of all test temperatures of the peak-aged aluminum alloy AA6110 were summarized and plotted in the stress amplitude-temperature diagram shown in Fig. 7. Below the obtained boundary, the deep-rolling process effectively enhances fatigue lifetimes. In contrast, if this boundary is exceeded, deep-rolling becomes ineffective.

Fig. 5 Cyclic deformation curves of the non- and deep-rolled, under-aged aluminum alloy AA6110 at 160°C

Fig. 6 The s - N curves of the non- and deep-rolled, peak-aged aluminum alloy AA6110 at room temperature and at 160°C

Fig. 7 The effective boundary of the deep-rolling process applied to the peak-aged aluminum alloy AA6110

Macroscopic compressive residual stresses or work hardening states (FWHM values) of the deep-rolled specimens, which were subject to fatigue testing below and above the effective boundary, still require clarification. Numerous fatigue tests performed on the non- and deep-rolled aluminum alloys AA5083 and peak-aged AA6110 are provided in Table 1. The fatigue lifetimes (number of cycles to failure, N_f) shown in Table 1 were plotted in one diagram in Fig. 8. Deep-rolling process can dramatically enhance the fatigue lifetime of the aluminum alloys AA5083 and AA6110 if the applied stress amplitude and temperature are appropriate.

In order to investigate the relaxation phenomena of the residual stresses and FWHM, the compressive residual stresses and work hardening states of the deep-rolled aluminum alloys AA5083 and peak-aged AA6110 were measured before and after fatigue testing (not until material

Fig. 8 Effectiveness of the deep-rolling process in various test conditions (for details, see Table 1). (*) indicates cases in which deep-rolling is ineffective

failure occurred), and were then plotted in Figs. 9 and 10. A correlation between the fatigue lifetimes, residual stresses, and work hardening states can be observed. The deep-rolling treatment can enhance the fatigue lifetime of aluminum alloys even though the residual stresses relaxed significantly, even up to about 60% (see Figs. 8 and 9). In contrast, the stability of the work hardening states is very crucial for an effective deep-rolling process used on aluminum alloys. If FWHM values decrease by more than approximately 5%, the deep-rolling process becomes ineffective (see Fig. 10). Therefore, it can be concluded that the stability of the work hardening states near the surface is the major influencing parameter to enhance the fatigue lifetime of the deep-rolled aluminum alloys, since fatigue damage primarily causes crack initiation.

Table 1 Testing conditions for investigations of residual stress and work hardening stability and the effectiveness of deep-rolling process

Num-ber	Alloy	Condi-tion	Test temperature (°C)	σ_a (MPa)	Number of test cycles	N_f of polished	N_f of deep-rolled

MODIFIED MECHANICAL SURFACE TREATMENTS

The modified mechanical surface treatments combine mechanical and thermal treatments near the surface to achieve an optimized surface condition. The strain aging concept is used on ferrous metals, especially for steels, to optimize their surface. Many steels are reported to have superior fatigue properties after the deep-rolling (or shot peening) process that is followed by an annealing process, and after optimized, high-temperature deep-rolling (or warm shot peening), and this has been described in detail in.^[16–21] An obstruction of dislocation movements by solute atoms and very fine carbides causes the stabilization of the residual stresses and the work hardening states near

the surface, which results in higher fatigue lifetimes.^[19] In the case of heat treatable materials, such as aluminum and titanium alloys, classical mechanical surface treatment is usually performed after an aging treatment to enhance the fatigue lifetimes. The modified surface treatment might be applied to the (as-quenched) aluminum alloys that were solution annealed. The heat treatment process (performed after mechanical surface treatment) or high-temperature mechanical surface treatment provides some heat to form static or dynamic precipitates in the work-hardened surface regions. However, it is still questionable whether the provided heat and time are sufficient to fully develop precipitates. Moreover, the compressive residual stresses and work hardening states should more or less be affected by the thermal relaxation. The deep-rolled, as-quenched aluminum alloy AA6110, which was annealed at a temperature of 160°C for about 12 h (optimized condition), was cyclically deformed in comparison to the non-deep-rolled and as-quenched, deep-rolled and as-quenched, and deep-rolled and peak-aged aluminum alloys shown in Fig. 11. The deep-rolling process can enhance the fatigue lifetime of the as-quenched aluminum alloy AA6110, especially in the high-cycle fatigue regimes due to generated compressive residual stresses and work hardening states as mentioned in the previous section. After annealing at 160°C for about 12 h, the fatigue lifetimes of the deep-rolled, as-quenched material improved, especially in the low-cycle fatigue regime. However, the deep-rolling process performed after a suitable/optimized aging treatment can completely combine the work of precipitation hardening and compressive residual stresses in near-surface regions of aluminum alloy AA6110 into an optimized microstructure, and, thus, can result in the best surface properties and fatigue lifetimes of the investigated aluminum alloy AA6110.^[12] In contrast, in the case of some aluminum and titanium alloys, mechanical surface treatment followed by an appropriate

Fig. 11 The s - N curves of the non- and deep-rolled, as-quenched aluminum alloy AA6110 in comparison to the deep-rolled, peak-aged and modified deep-rolled alloys

Fig. 12 The s - N curves of the high-temperature, deep-rolled aluminum alloy AA6110 compared to the deep-rolled, peak-aged alloy

annealing process can enhance their fatigue lifetimes as explained in depth in.^[13–15] Therefore, there are several important factors that affect the effectiveness of the modified mechanical surface treatments, i.e., the amount of plastic deformation near the surface (related to the type of mechanical surface treatments), the work hardening ability, the relaxation behavior (related to the type of materials and its structure), and an increase in surface hardness after aging treatment (categorized by the class and chemical composition of the investigated materials).^[12]

Another modified mechanical surface treatment, namely a deep-rolling process at a high temperature, was investigated for the as-quenched aluminum alloy AA6110, see Fig. 12. The high temperature deep-rolling process creates an insignificant fatigue lifetime enhancement. Static/dynamic precipitates certainly occurred during the deep-rolling process performed at an elevated temperature. However, the formed precipitates were not fully effective because the deep-rolling process was too short. Moreover, static/dynamic recovery processes decreased macroscopic compressive residual stresses and work hardening states during the deep-rolling performed at an elevated temperature.^[26]

SUMMARY

The fatigue performance and behavior of the non- and deep-rolled aluminum alloys AA5083 and AA6110 at room temperature and elevated temperatures were investigated and discussed. Modified deep-rolling treatments, i.e., deep-rolling followed by an annealing process and high-temperature deep-rolling, were performed on the as-quenched aluminum alloy AA6110. The results of the investigation can be summed up as follows:

1. The cyclic deformation curves of the non- and deep-rolled aluminum alloys AA5083 and AA6110 are governed by dislocation–dislocation and dislocation–precipitation interactions during cyclic loading.
2. At applied stress amplitudes below a threshold stress amplitude at a given temperature, the fatigue lifetimes of aluminum alloys AA5083 and AA6110 can be enhanced by the mechanical surface treatment of a deep-rolling process owing to the stability of the work hardening states prolonging the fatigue lifetime. In contrast, macroscopic, compressive residual stresses relax markedly.
3. Modified deep-rolling processes, i.e., deep-rolling followed by annealing and high-temperature deep-rolling fatigue, are alternative methods for enhancing the fatigue lifetime of as-quenched aluminum alloy AA6110, but they are not nearly as effective as deep-rolling of peak-aged states.
4. The deep-rolling process performed after a suitable/optimized aging treatment can completely combine the work of precipitation hardening and compressive residual stresses in regions near the surface of aluminum alloy AA6110 into an optimized microstructure, and, thus, can result in the best surface properties and fatigue lifetimes obtained for the investigated aluminum alloy AA6110.

Abstract

The present work reports findings for the application of specialized aerospace aluminum rivets, manufactured from Al 7075 (Al-Zn-Mg-Cu) T6 alloy stem/mandrel, with an Al 5056 (Al-Mg) shank or sleeve, which were used for construction rectification of an outdoor louver façade on a high-rise building. These specialized rivets were used to replace failed conventional construction rivets, which consisted of sleeve and mandrel comprised of either all-steel, all-aluminum, or aluminum-steel. The building is in close vicinity to the ocean and exposed to extremely high wind loading, making the rivets susceptible to failure by corrosion and fatigue. The focus of the present work is to report the examination of the specialized replacement rivets following an in-service lifetime of 12 years. The examination revealed that the replacement rivets (mandrel and sleeve) remained intact and uncontaminated, essentially free of corrosion. It is likely that sunlight exposure and the composite nature of the rivets enhanced the performance through age hardening. Analysis of the rivets included visual inspection, optical microscopy, Vickers microhardness testing, and transmission electron microscopy. The aim of the analysis was to correlate microstructures with microhardnesses, using these data to evaluate the ultimate tensile strength (UTS), yield strength (YS), and the potential for further age hardening. The Vickers microhardnesses were observed to have increased by ~8% over the service lifetime of 12 years, which equates to increases in YS (34.8–46.8 MPa) and UTS (23.8–45.6 MPa). Although the results show that there is a large increase in the strength values when comparing the unused rivets to the 12-year-old rivets, this increase in hardness may not necessarily be due purely to natural aging kinetics such as exposure from the sun and outdoor temperature. However, there appears to be some insignificant alteration of the microstructure and mechanical properties as a result of this exposure.

INTRODUCTION

Background to Aerospace Aluminum Rivets

Pure aluminum in the annealed condition has a low yield strength (YS) of 7–11 MPa.^[1] However, the addition of small amounts of specific alloying elements can increase the YS to 200–600 MPa or more.^[1] Age hardening also can enhance the YS as high as 450–600 MPa.^[2] There are two major groups of wrought aluminum alloys, which are age hardenable and non-age hardenable.^[3] When heat

treated, the YS of age-hardenable alloys can increase owing to: (1) precipitation hardening (the primary mechanism for strengthening of aluminum alloys), (2) solid solution hardening or strengthening, (3) strain hardening or work hardening, and/or (4) refinement of the grain size or grain structure (grain boundary strengthening).^[2,4] The combination of low cost, lightweight, ductility, high strength, and toughness makes age-hardenable alloys suitable for uses as structural and semistructural parts in aircraft.^[5] The Al 7000 series alloys are used commonly in a wide range of applications in aerospace.^[2]

Current Applications of Aerospace Rivets in Mechanical and Structural Applications

The use of rivets in aerospace construction is a well-established practice.^[6–9] The first use of aluminum rivets in aircraft was in 1936 in the United States by Cherry Aerospace.^[10] Table 1 gives some of the mechanical properties of aluminum alloys that are used commonly in aerospace rivets.

Rivets are used widely to join materials used in aerospace applications. These rivets generally are equivalent in chemical composition and mechanical properties to the materials they join together. An industry rule of thumb is that the number of blind rivets used in an aircraft is five blind rivets to three solid rivets of the same diameter.^[16] Although a blind rivet is not as strong as a solid rivet, it has clear advantages in ease of installation over other types of fasteners, and it is not susceptible to vibrational loosening.^[17] Fig. 1 illustrates the aerospace rivet used in the present work. Fig. 2 illustrates a cross section of an installed rivet and some of the characteristics deriving from its design.

Fasteners are an important integral component in the assembly of an aircraft structure, and there are thousands of fasteners and rivets used in the construction of most aircraft.^[18,19] However, in order to understand how fasteners or rivets affect the performance of specific structures of an

aircraft, the member components must be deconstructed, defined, and quantified so that their interactions both within the member and between members are understood. In an aircraft, there are many engineering variables that represent major challenges to the designer in classifying the vast amount of materials employed according to specific grade and type of materials, physical and chemical characteristics, joining of materials, ensuring their compatibility to mitigate galvanic corrosion, fluctuating loads, and other variables.

Background to Refurbishment Using Specialized Rivets in Façade: Design and Construction

Rivets are used not only in the construction of aircraft but also routinely in the building industry. Although it is apparent that aerospace rivets offer superior performance in terms of corrosion resistance and mechanical stability,

Fig. 1 Aerospace rivet used in present work^[17]

Fig. 2 Cross section of installed rivet and characteristics: 1 = Flush installation makes fastener easier to paint and resistant to salt and water, 2 = Flush pin break eliminates need for grinding/filing, 3 = Solid-circle lock ensures maximal strength and resistance to vibration—designed to resist pin pushout, 4 = Sleeve expands during installation, tightly filling hole to create a weather-resistant joint

Extrudable
Al-Si-Mg-Hall-Heroult

their use in structural applications remains limited. This is likely a result of limited experience with these products and, more importantly, higher costs.

The present work reports rectification done on an external roof façade in which the existing rivets had aluminum sleeves and steel mandrels, the latter of which had corroded and degraded mechanically such that the load was carried by the aluminum sleeve and so failure of the louver system occurred. The rectification by Melhem et al.^[11] involved the use of an Al 7075 rivet pin with an Al 5056 sleeve. The rivets were used to join aluminum louver mullions and profiles of grades 6060, 6063, and steel brackets on a multistorey building. The work was completed in June 2005, and the installation has been monitored continuously since then. More than 10,000 rivets were used in this work to join the louvers as well as custom-designed aluminum sections that consisted of 6063, 6060, 6061, and Al 6351. Al 7075 rivet pin (with gold chromate coating) with Al 5056 sleeve (with clear chromate coating), with 3/16" (4.73 mm) diameter, was utilized since these materials are compatible from a galvanic perspective for the joining of the aluminum façade structures on the building. Furthermore, Table 1 reveals that the rivets used have exceptionally high tensile and shear properties.

Corrosion

In general, corrosion rates of single-phase aluminum alloys are low.^[20] However, the corrosion rate of aluminum alloys increases once a second phase has precipitated. The continued growth of the precipitates suggests that their eventual coalescence would result in a decrease in corrosion owing to alteration overall decrease in the surface area of the galvanic cell. In fact, some alloys exhibit maximal corrosion when in the overaged condition.^[20] Furthermore, cold working can enhance corrosion since the metal is highly stressed, thus generating dislocations that promote the heterogeneous nucleation of precipitates during aging.^[20] Also, the Al 5000 series of non-heat-treatable aluminum alloys is more susceptible to stress corrosion cracking when cold worked.^[21]

It is clear that the susceptibility to environmental corrosion depends on a range of factors, which included heat treatment and mechanical working, chemical composition, mineralogical composition, microstructure, and environmental factors (e.g., temperature, wind fatigue). Corrosion usually is initiated by the presence of rainwater, condensed humidity, seawater, and/or sea spray, which can initiate electrochemical reactions due to anodic corrosion or galvanic corrosion. However, as indicated previously, heat-treatable aluminum alloys (e.g., Al-Zn-Mg-Cu), such as Al 7075, may undergo changes in their properties continually with time, depending on a number of factors, resulting in YS as high as 500–505 MPa.^[2,22] In contrast, non-heat-treatable alloys (e.g., Al-Mg-Mn), such as Al

5056, are not affected by heat, but they can be strengthened by work hardening or cold working, resulting in YS 150–405 MPa.^[23]

When sodium chloride is present in the environment, crevice corrosion, where water and corrosive contaminants remain trapped in narrow gaps, may occur. Since rivet design incorporates such internal gaps, the risk of this type of corrosion is inevitable. Sealing or welding may help reduce this potential.

Al 7075 is susceptible to embrittlement due to microsegregation of MgZn₂ precipitates, which leads to catastrophic failure.^[24] Simultaneously, its resistances to oxidation and pitting corrosion are reduced in corrosive environments.^[25] Consequently, Al 7075 in the T6 condition should not be used in aggressive environments unless protected by anodizing, chromate coating, or painting.

The distribution of second-phase material has a significant influence on the corrosion behavior of high-strength aluminum alloys. If second phases are located preferentially at grain boundaries, they may promote intergranular corrosion (IGC) owing to their compositions and hence half-cell potential differences with the adjacent alloy matrix.^[26] Furthermore, the narrow band on either side of the grain boundary, which is a precipitate-free zone (PFZ), also influences the corrosion behavior of aluminum alloys since the PFZ is depleted of alloying elements, again establishing half-cell potential difference. Consequently, IGC of high-strength aluminum alloys often is attributed to compositionally different features at the grain boundary and associated anodic dissolution of (1) the PFZ, where noble alloying elements, such as copper, are depleted; (2) anodic second phase precipitates at the grain boundaries; or (3) segregated alloying elements, such as magnesium or impurity elements, at the grain boundaries. In the Al 7000 series, in which anodic precipitates, such as MgZn₂, are formed at the grain boundaries, these precipitates are relatively active in relation to the alloy matrix,^[26] so IGC occurs. The associated precipitation occurs as both heterogeneous and homogenous. In the former, the YS increases at the grain boundaries or isolated precipitation sites, so this type of precipitation does not contribute to strengthening of the grains. In the latter, the precipitates in the grains are coherent or semi-coherent, so they exert minimal strain, thereby allowing hardening within the grains to occur.

EXPERIMENTAL PROCEDURE AND OBSERVATIONS

Site Investigation

The present work is based upon a case study that was conducted initially in early January 2005 on a high-rise building close to the coast in Sydney, Australia. Generally, locations within 8–16 km of saltwater are considered coastal since the wind can carry the salt much further than

16 km.^[27] It had experienced a major corrosion failure of the structural steel roof and aluminum louver façade in August 2003. The failure occurred on Level 29, which was the roof top, owing to extreme wind speeds in the 100–120 km/h range. The roof and façade failed, as indicated in Fig. 3, which resulted in debris falling on the south aspect into a childcare center and public footpath. This occurred on the weekend, and there were no injuries or fatalities.

The failure occurred well before the design life of the building. Examination of the failed sections revealed extensive corrosion, largely owing to design flaws in the form of joining aluminum louvers to structural steel. The façade louvers failed from galvanic corrosion as the louver mullions and profiles were joined with rivets with Al 5056 aluminum sleeves and steel mandrels. Chemical analyses by inductively coupled plasma atomic emission spectrometry revealed that the mullion was made of Al 6063 and the louver was made of Al 6060.

The replacement of the existing steel/aluminum rivets with aerospace Al 7075/Al 5056 rivets in the rooftop

(Level 29) and façade (Levels 26–28) was completed in June 2005. The building has been inspected regularly in order to confirm that the rectification remained both intact and corrosion-free. The last inspection was carried out on March 29, 2017. At that time, several of the Al 7075/Al 5056 rivets were extracted from various locations around the building. Replacement rivets were identical to those used in the original rectification. Visual inspection revealed no obvious damage or apparent corrosion to either the rivets or aluminum structures. As suggested in Fig. 4, the rivets appeared to be in pristine condition. These images may be contrasted with the appearance of the structure following rectification in June 2005, shown in Figs. 5–7.

Wind Load on Structure

Despite the high wind speeds to which the structure was subjected, the wind loading imposed and translated to the rivets was calculated to be quite low and within an acceptable range to withstand failures or pullout of the rivets.^[28]

However, wind loading is complicated in that it may involve a combination of tensile, compressive, and shear stresses. This is particularly the case since the wind pressure for the building shape was considered to include both positive (wind blowing directly on the building, thus creating forward pressure) and negative (wind passing the building, thus creating a negative back pressure). The fluctuating wind loads were calculated for the louver structures during the initial investigation according to *Australian Standard AS 1170 Part 2–2002. Minimum Design Loads on Structures, Part 2: Wind Loads*.

Rivet Installation

Although the wind loading may have had a small effect on the sleeves by subjecting them to modest mechanical forces, it is likely that most of the work hardening occurred in the sleeve surface when the rivet was installed. As shown in Fig. 8, the rivet mandrel is pulled by the rivet gun through the sleeve, but the mandrel head is of wider diameter than the sleeve, thereby expanding the tail. These actions force together the two sheets being joined and clamp them tightly. The serrations on the mandrel are gripped tightly by the rivet gun, which is positioned directly on the workpiece. This prevents any movement, vibration, or pin pushout. With further pulling by the rivet gun, the mandrel is snapped at the groove. The most successful aerospace rivet probably is the *Huck Magna-Lok®*, which is manufactured by Alcoa Fastening Systems.^[29]

Sample Acquisition

Thirty-two rivets were extracted from diverse locations in order to achieve a representative sampling of the 12-year-old rivets exposed to the four cardinal directions as shown in Figs. 9 and 10. Approximately half of the rivets were drilled from the head section of the rivet, and the other half were drilled from the blind section in order to be able to examine the non-drilled sections for the entire rivet length. A 3-mm-diameter drill bit was used for this.

Sample Selection

Two typical rivets in service for ~12 years (Samples 1 and 2) were selected for extended analysis. A new rivet (Sample 3) was purchased from a supplier under the assumption that it had been manufactured relatively recently. All rivets were comprised of Al 7075 sleeve and Al 5056 mandrel.

Fig. 10 Installation of new replacement rivets where 12-year-old rivets were extracted in March 2017

Sample Preparation

The rivets were prepared by sectioning with a Struers Minotom diamond saw, which uses cooling oil. They then were cold mounted and polished by standard metallographic preparation methods. Cold mounting is used in order that the temperatures due to hot mounting (similar to aging) and any other thermal influence that alters the grain boundaries are completely avoided. A *Buehler Cold*

Mounting unit was used to prepare the resin holding the sectioned rivet, and this was prepared with 1 part hardener to 4 parts epoxy. The resin solution was stirred by hand until it was sufficiently transparent. Samples were placed inside a vacuum pump for 5 min so that any excess air bubbles would be removed. The prepared samples were left overnight to harden in the resin moulds, and the samples were coated with a thin layer of vaseline for lubrication and to aid in easy extraction from the mould.

Four levels of grinding were carried out using the successfully finer silicon-carbide pads of the following grit levels or grades: 120, 320, 1200, and 2500. Grinding was carried out at low speeds of 200 rpm on a *Struers Labopol 5* until the sample surface was coplanar. The samples were then cleaned thoroughly prior to polishing, and this was achieved by carefully rubbing the surface with cotton wool under running water, followed by immersion in a soapy water mixture in an ultrasonic bath for 2 min. Samples were dried by the addition of ethanol to the sample surface, followed by blow-drying using compressed air. Polishing was carried out on a *Struers Labopol* five machines at a low 150 rpm. Polishing began at 3 micron (μm) using 3 μm oil-based polycrystalline Kemet Diamond suspension on a Kemet NSH-BM polishing pad, followed by 1 μm using 1/10 μm oil-based polycrystalline Kemet Diamond suspension. The polishing process was finished using oxide polishing-colloidal silica suspension and a Kemet Chem-HM polishing pad. The polished surface was

checked between polishing stages on an Olympus PMG 3 microscope at 25× magnification.

The polished surface was checked prior to etching on a *Nikon Epiphot 200 microscope* at 100× magnification. The samples were etched with Keller's Reagent (1.5 mL HCl, 1.0 mL HF, 2.5 mL HNO₃, 95 mL distilled water), where the samples were immersed in the solution for 30 s prior to being cleaned by ethanol. The etching process was carried out under a fume hood at room temperature.

Figures 11–13 show a schematic of the cross sections of the samples that were sectioned and prepared using a diamond blade for analysis. The nomenclature uses the formalism in which the first number refers to the sample (1, 2, or 3) and the second number identifies the location of the analysis.

Testing

Vickers Microhardness

The Vickers microhardness measurements were performed using a *Stuers Durosca G5* with a weight of 300 g applied

Correlations of Vickers Microhardnesses with YS and Ultimate Tensile Strength

The Vickers microhardness can be converted to YS and ultimate tensile strength (UTS) through the use of empirical equations. Equations were created from data provided by Pagliarello.^[30] Equations devised by Clark et al.^[31] for altered 7075-T6 specimens were also used. The empirical equations are shown in Eqs. 1–5, where Eq. 1 provides the conversion of ‘Vickers Hardness Number’ (VHN) hardness to ‘Hardness-Rockwell B’ (HRB) (All of these approaches require conversion of the Vickers microhardness to the Rockwell B hardness, which was done using the data of *ISO 18265:2013 Metallic Materials—Conversion of Hardness Values*), Eqs. 2 and 3 provide the calculation for YS and UTS, respectively, by Pagliarello,^[30] and Eqs. 4 and 5 provide the calculation for YS and UTS, respectively, by Clark et al.;^[31]

$$\text{HRB} = 0.3 \times H_v + 34.987 \quad (140 \leq H_v \leq 195),$$

using the data of *ISO 18265:2013 Metallic Materials: Conversion of Hardness Values*)

(1)

$$\text{YS} = 9.75 \times \text{HRB} - 388.19^{[31]}$$
(2)

$$\text{UTS} = 9.49 \times \text{HRB} - 273.64^{[31]}$$
(3)

$$\text{YS} = 8.92 \times \text{HRB} - 309.95^{[32]}$$
(4)

$$\text{UTS} = 6.11 \times \text{HRB} + 0.76^{[32]}$$
(5)

The results of these conversions are given in Tables 4 and 5. It can be seen that the data for YS agree relatively well, whereas the data for UTS are in less agreement.

Table 6 contrasts UTS values calculated on the basis of Pagliarello and Clark et al.^[30,31] using data from other researchers.^[32–35] Table 7 provides further contextual information in the form of experimental data for the mechanical properties of interest.

Optical Metallography

The optical microscopy images are shown in Figs. 14–16.

Table 8 summarizes the observations made for Figs. 14–16, and it contrasts the microstructural feature with the mechanical properties.

Transmission Electron Microscopy

Specimen Preparation

Transmission electron microscopy (TEM) samples of the Al 7075 mandrel were prepared by focused ion beam microscopy using the external lift-out method^[38] using an FEI *Nanolab 200*. The surfaces of the specimens were protected using *in situ* platinum deposition prior to application of the ion beam. The sample locations were adjacent to those designated as 2.7 and 2.8 in Fig. 12. The samples were examined using an FEI *Tecnaï GS* at an accelerating voltage of 200 kV.

TEM Data

The TEM images that were obtained to contrast the 12-year-old rivets with the new rivets are shown in

Fig. 14 Sample 1 (12 years old): (a) Central section of mandrel (Al 7075), showing non-equiaxed grains and randomly located $MgZn_2$ precipitates (dark regions); (b) typical section of sleeve (Al 5056), showing elongated grains indicative of rolling

Fig. 15 Sample 2 (12 years old): (a) Central section of mandrel (Al 7075); (b) typical section of sleeve (Al 5056), showing elongated grains with pronounced flow, indicating plastic flow

Fig. 16 Sample 3 (new): (a) Central section of mandrel (Al 7075), showing irregular α -Al grains and MgZn_2 precipitates (dark regions); (b) typical section of sleeve (Al 5056)

Figs. 17 and 18. Unit scales for images are shown as follows: $a = 500 \text{ nm}$, $b = 200 \text{ nm}$, and $c = 500 \text{ nm}$, respectively.

TEM Observations

Examination of the mandrel section of 12-year-old rivets (Sample 1) revealed a microstructure comprising a dispersion of Mg-Zn-rich particles (MgZn_2 precipitates), which probably are η' . These features are consistent with the microstructures observed by Li et al.^[39] in Al 7075 samples aged at 120°C for 24 h. The selected area electron diffraction (SAED) pattern recorded from the $\langle 001 \rangle$ aluminum zone axis showed, as expected, strong reflections from the aluminum matrix; no additional reflections or diffraction contrast from the second-phase particles was

observed. This suggests that any diffraction contrast arising from the precipitates was too weak to be present in the SAED pattern.

Examination of the mandrel section in the new rivet (Sample 3) revealed a microstructure that was broadly similar to that of the 12-year-old rivets. It consisted of fine nanoscale precipitates together with a dispersion of coarser particles. The SAED pattern was essentially identical to that of the other rivet.

More detailed examination of the precipitate distribution in the 12-year-old rivet suggests that there is a small decrease in the size of the coarser Mg-Zn-rich particles. Comparison of the TEM images suggests that in the new rivet, these coarser particles are slightly larger than $\sim 50 \text{ nm}$, whereas, after the in-service lifetime, these particles

Fig. 17 Sample 1 (12 years old): (a) Bright-field TEM image in mandrel section, showing grain boundary and MgZn_2 precipitates ($\sim 25\text{--}50$ nm) throughout grains (dark spherical and rodlike); (b) bright-field TEM image, showing MgZn_2 precipitated mostly within grains (dark spherical and η' rodlike); (c) selected areas of electron diffraction pattern oriented parallel to $\langle 001 \rangle$ axis of Al matrix

Fig. 18 Sample 3 (new): (a) Bright-field TEM image in mandrel section, showing MgZn_2 precipitates ($\sim 50\text{--}100$ nm) throughout grains (dark spherical and rodlike); (b) bright-field TEM image, showing MgZn_2 precipitated mostly within grains (dark spherical and rodlike); (c) SAED pattern oriented parallel to $\langle 001 \rangle$ axis of Al matrix

are slightly smaller than ~ 50 nm. The particles in the 12-year-old rivet also appear to be slightly more spherical than those in the new rivet. These observations are consistent with some reversion of the precipitate particles over time as observed in the 12-year-old rivets. In contrast, there were no obvious differences in the size or distribution of the η' particles between the samples representing the 12-year-old rivets and new rivets.

As shown in Fig. 17a,b, the TEM image of the 12-year-old rivet included a grain boundary. It can be seen that there is no evidence of PFZs or enriched grain boundary precipitation.

DISCUSSION

The main interest of the present work lies in its examination of the effect of long-term environmental aging of aerospace rivets used for construction purposes. The conditions of exposure had the potential to be relatively severe in that they involved cyclic heating from sunlight, irregular wind loading, exposure to rainwater, and sea spray. Hence, the rivets would have been subjected to various stresses such as tensile, compressive, and shear as a result of the wind loading acting upon them. Furthermore, the conditions for corrosion clearly were present, and there does not appear to be equivalent data in the literature.

From Table 8 in “Optical Metallography” section, the summary of the grain size and Vickers microhardness indicate that the Al 5056 sleeve material experienced mechanical working since the grains were elongated. The average microhardnesses of the 12-year-old Al 5056 sleeve were Sample 1 111 Hv and Sample 2 108 Hv, whereas the average microhardness of the new sleeve was 104 Hv, giving a difference of 4–7 Hv and a decrease of $\sim 4\%\text{--}7\%$. In contrast, the average microhardnesses of the 12-year-old Al 7075 mandrel were Sample 1 184 Hv and Sample 2 181 Hv, whereas the average microhardness of the new mandrel was 168 Hv, giving a greater difference of 13–16 Hv and a decrease of $\sim 7\%\text{--}10\%$. Although the reason for the differential in the microhardness decreases of the two alloys is unknown, it is probable that this derives from a combination of the different characteristics of the alloys and the stress and corrosion conditions to which they were subjected.

Optical microscopy revealed that the Al 5056 sleeve exhibited elongated grains owing to rolling or grain flow around the curved section near the rivet head, both of which are indicative of plastic flow during the extrusion process. The grain shapes and sizes of the 12-year-old and new sleeves were essentially identical, so it is not surprising that microhardnesses are similar. Figs. 14a, 15a, and 16a represent the mandrel of Al 7075 for samples 1, 2, and 3, respectively. Optical microscopy shows that the 12-year-old mandrels (Figs. 14a and 15a) exhibited

grain lengths in the 30–70 μm range and widths in the 3–35 μm range. However, the new mandrels (Fig. 16a) exhibited grain lengths of 15–50 μm and widths of 5–40 μm . In effect, the new mandrels appear to consist of nearly equiaxed but larger grains.

In the TEM images, the dark regions representing MgZn_2 inclusions are variable in size and are in the cross-section range $\sim 1\text{--}5\ \mu\text{m}$. Their distribution is relatively uniform and essentially the same for both the 12-year-old (Figs. 14a and 15a) and new (Fig. 16a) mandrels. Most of these precipitates in the mandrel sections of the 12-year-old rivets generally are spheroidal (see Figs. 17 and 18), with some rod-shaped precipitates also present. The relatively uniform distribution of precipitates suggests the homogeneous nucleation of Guinier–Preston (GP) zone precipitates, which could provide solute strengthening. There also may be a slight hardening effect during aging due to a reversal process.

The TEM images show that the new rivets contained nanoscale η' precipitates as well as coarser Mg–Zn-rich particles that were approximately in the few tens of nanometers in diameter. These microstructural characteristics are similar to those reported by other researchers^[39] for Al 7075 aged at 120°C for 24 h. The 12-year-old rivets revealed a microstructure that was similar to that of the new rivets in that there were no PFZs or enriched grain boundary precipitation. The only major difference is that the 12-year-old rivets exhibited precipitates (Fig. 17a,b) that were slightly smaller than those of the new rivets (Fig. 18a,b). This probably is due to slight variations in production compositions and conditions.

As cyclic exposure to heating from sunlight was a component of the aging process, an interesting point is whether such aging may take place in the future. This appears to be a distinct possibility since it is known that the kinetics of aging of Al 7075 apply over many years, even at room temperature.^[40] Furthermore, the dissolution rate of the precipitates may be a relevant factor, albeit probably at a very slow rate. These issues impact on the potential for further hardening and strengthening and are important owing to the desirability of increasing both the mechanical properties and the corrosion resistance. The Al 7000 series alloys attain high strengths in the T6 condition, but their corrosion resistance is poorest in this condition.^[39] Conversely, the corrosion resistance is increased when the alloy is overaged in conditions such as T73, T76, or T74.

Since the mandrels originally were subjected to a T6 temper, further substantial improvements in the mechanical properties would not be expected. However, it is clear that the mandrels, rather than degrading, have obtained just such increases in the microhardness, YS, and UTS. Both the optical microscopy and TEM images reveal that some dissolution of the MgZn_2 in the mandrels has occurred over time. Although most studies have reported natural aging effects following solutionizing, a key study

found that the precipitate size in solutionized Al 7075 actually increased to 1.2 nm after natural aging for 25 years according to Hatch.^[41] In this study, there was a corresponding YS increase from the quenched condition, increasing from 150 to 465 MPa, the latter of which is nearly that is achievable in the T6 condition.^[41] The GP zone precipitate size in the T6 condition generally is in the 2.0–3.5 nm range, and the microstructure also contains traces of hexagonal metastable phases which is rich in Zn and Mg. These features are generally consistent with those of the present work for both the 12-year-old and new rivets. However, in the present work, the MgZn_2 precipitates are larger at 50–100 nm, although there is also a dispersion of finer precipitates in the 1–3 nm range. Concerning the dispersion of finer precipitates as Hatch describes,^[41] this is only comparable with the nanoscale precipitates observed in both the new and old rivets evidencing the T6 treatment.

Therefore, the presence of the dispersion of finer precipitates in both the 12-year-old and new rivets suggests that they were treated in the T6 condition. If so, then the present work reveals that the principal physical and microstructural changes are reflected in the decrease in the size of the precipitates, which resulted in a corresponding increase in microhardness of the mandrels, and the absence of corrosion.

It appears that the precipitates are larger in the new rivets when contrasted to the precipitates observed in the 12-year-old rivets. It would be misleading though, to compare the new rivets with the 12-year-old rivets and then argue that the older rivets became harder by such a large difference due to aging kinetics occurring as a result of being exposed to the outdoor temperature over the 12-year period. Also, it is not necessarily incorrect to infer from this, however, that natural aging is definitely not a contributing factor for the increase in hardness and strength.

It would be expected that the substantial gains in YS (34.8–46.8 MPa) and UTS (23.8–45.6 MPa) would be reflected in microstructural changes, although these appear to be minimal. However, these changes are a direct reflection of the microhardnesses, which generally are viewed as being strongly dependent on the microstructure. The properties of the coarser metastable η' phase in the unused rivets may be compared to those of Vijaya et al.^[41] where it has been proposed that the coarsening of the precipitates and its dissolution leads to a reduction in hardness.

This notion is substantiated by Hudson^[37] where specimens of 7075-T6 aluminum alloys were compared to the properties in the same alloy some 19 years later, i.e., the first tests were conducted in 1949, and the later tests were conducted in 1968. It was shown that there was a slight change in tensile properties over time in service, and that there was a small increase in yield and UTS (5 and 2 MPa, respectively). A fatigue study also showed that there were negligible differences of fatigue performance of the

aluminum alloy when it was first tested in 1949 to when it was again tested later in 1968. The calculated change in the YS was attributed to natural age hardening kinetics.

Although the hardness test can be a good indicator for the tensile and YS of the material, materials exhibiting defects such as corrosion or cracks will tend to reduce the tensile strength of the material holistically. The assumption behind the generalized empirical equation is that the given material must be reasonably homogeneous from a structural or solid mechanics perspective, because material defects will create stress concentrations leading to failure below expected tensile strength values for the given material. However, given that the hardness results are typical and agree well with the literature, visual, microscopy, and TEM analysis further provided evidence that corrosion is not at all present, hence it is suggested that the rivets are corrosion free. Hardness tests on slightly corroded (very small amounts of corrosion) 7075 specimens have been found to yield significantly much lower hardness and lower UTS values than the expected hardness readings as per Obert et al.^[32] The hardness results for the rivets in this article therefore were not lower, but rather high when comparing to most aluminum alloys, and they were in agreement with the results in the literature. This validated almost with complete certainty that no corrosion could have been present on the rivets surface nor within the subsurface regions.

The literature seems to shy away from case studies or details regarding sleeves of rivets, and the sleeves are no less important to the rivet structure than the mandrel itself. Basically, the integrity of the sleeve is what holds the entire rivet together and is the direct interface holding the structure in place, since we have seen directly what happened to the failed high-rise building roof structure in 2003 when the failed rivets (made from steel mandrel with aluminum sleeves) were assessed. The poor design for these original rivets in the building, meant that the steel mandrel which inevitably corroded leaving intact only the aluminum sleeve, did not have the required strength to hold up the structures, and this was one of the main reasons for the catastrophic failure. Rivets are therefore rendered futile once either of the components—mandrel or sleeve—deteriorates, and they must act together to fulfill the requirements.

During the installation of the rivet (see Fig. 19), from left to right, the malleable hollow sleeve (dark gray) expands and forms around the contours of the mandrel blind head (light gray bulge at the bottom of Fig. 19 far right) to take up any slack as the mandrel is pulled through the sleeve, and the sleeve tightly fills the hole that was drilled. On the opposite end of the blind head as shown in Fig. 19 (last two on the right side), the mandrel snaps once the tensile strength of the mandrel alloy can no longer overcome the resisting force securing the blind head in place against the pieces being riveted. This clamping action is what allows the relatively stronger 7075 mandrel to shape or extrude the more malleable 5056 sleeve so that the end is plugged and prevents ingress of water, chlorine, and other air-borne contaminants. The level of extrusion in the sleeve while being formed in shape around the blind head is also subject to work hardening. The wind loading on the structure is also continually creating to some minor degree tensile, compressive, shear, and tribological action upon the sleeve. However, the level of work hardening here may also be minute, but difficult to qualify at this stage in the project.

There is little issue with galvanic corrosion between the mandrel and the sleeve as they are very close in the galvanic series and on the anodic side, since the solution potentials of the aluminum alloys 1000, 3000, 4000, 5000, 6000, and 7000 series are anodic, whereas 2000 series is cathodic. Furthermore, the rivets were coated with water-based paint on the side of where the mandrel snaps which provided further sealing. The 5000 series alloys have excellent resistance to corrosion in a marine environment, except when subjected to temperatures in excess of 60°C, and aluminum in general is resistant to corrosion when subjected to a pH range between 4.5 and 8.5 in comparison with steel, which would corrode at approximately 2–3 times that of aluminum in the same pH range. Generally, aluminum used in aerospace or external surfaces of buildings will be exposed to rain, and any accumulated salt on aluminum surface will be easily washed off, as is the case for these rivets since they are continually exposed to rain. However, the main disadvantage with aluminum with respect to electrolytes would be excessive exposure to higher than normal temperatures, but this was not a major concern for the authors with aluminum in the outdoor environment, as these temperatures are rarely experienced in Australia.

Abstract

Forging may be defined as a forming process of a blank (billet) which is put on a lower die to receive compressive force from an upper die and the resulting plastic flow is initiated to fill the die cavity. This article reviews various aspects of the forging processes including: basic forging operations including die forging design, defects, and forging presses.

Keywords: Defects; Design; Die forging; Forging processes; Presses.

INTRODUCTION

Since 1950 parts of cameras, bicycles, and tubes have been manufactured from aluminum as it is a light metal. After 1960, aluminum was applied for automobile parts because of its high strength to weight ratio. For examples, piston for racing motorcycles were forged from 4032 alloy at 400°C and valve lifter for sports cars were forged at room temperature. Fishing reels have been forged, since 1970, at room temperature and forged pistons for racing motor cars since around 1980.^[1] The amount of aluminum which was forged has increased since around 1970 after forging of aluminum wheels started. If we could find a much stronger aluminum alloy to be forged, for example by increasing the silicon content, aluminum application to the motor car industry could be accelerated. Forging can be defined as the forming process of the bulky blank which is put on the lower die to receive compressive force from the upper die and plastic metal flow is initiated to fill the die cavity constructed by the upper and lower dies. Or the forming process of billet which is put in a container will receive compressive force from a punch and plastic metal flow is initiated to flow out from the die orifice.

When upper and/or lower dies have flat surfaces, the process is called compressive or upsetting process. This is the simplest forging operation. As a blank or billet which suffers a big compressive force during forging operation, so forged products will have a much sounder structural quality. Even if the blank or billet contains some small voids insides, they will be closed during the forging operation which is done under high compressive

stress. Upsetting strain can be expressed by engineering strain e defined by

$$e = \frac{(h_0 - h)}{h} \quad (1)$$

or logarithmic strain ε defined by

$$\varepsilon = \ln\left(\frac{h_0}{h}\right) \quad (2)$$

h_0 and h denote the heights of the billet before and after upsetting (Fig. 1). Logarithmic strain is superior to express large strain, and is often used for forging operations, because material receives a large strain by forging operation. During small strain less than 0.1, engineering strain e is nearly equal to logarithmic strain ε .

The relation between true stress (flow stress) and logarithmic strain during upsetting is shown in Fig. 2. for annealed pure aluminum (99.7% Al, 18HV). Cylindrical aluminum billet was upset in a sub-press to keep the top and bottom surfaces of a billet parallel. The upsetting test was done on a hydraulic material testing machine at room temperature. The re-shape upsetting method^[2] was applied to keep the billet's height/diameter ratio between 1.5 and 0.5 during upsetting. When the h/d ratio is more than 1.5, sometimes billet will show buckling and when the h/d ratio is less than 0.5, the effect of frictional force between die and billet to flow stress will not be possible to neglect.

Generally speaking many forged products have strain between 2 and 4, so it will be easily understood that the forged product will have higher strength than the original material because of work hardening when forging

Fig. 1 Dimensions of test piece of upsetting test, friction free

Fig. 2 Flow stress versus logarithmic strain curve of pure aluminum

Fig. 3 Top view of rectangular parallel piped test piece of upsetting test, accompanied interfacial frictional force between tool and billet

has been done at room temperature. Flow stress is linked directly to each individual material components and testing conditions such as strain rate and temperature. If we do not know the flow stress–strain curve for the individual given materials, hardness could be helpful. Flow stress and hardness have very good mutual correlations. When there is friction between the die and the block during the upset of a rectangular parallelepiped, the distortion of the top surface of the block cannot be neglected. The top view after upsetting cannot be similar to the original rectangle, but more deformation along the shorter side will be observed (Fig. 3). Forged products could be complex shapes in one piece with continuous fiber flow and smooth surface. Forging process could be

the process which brings near net shape products with high productivity. Higher attention should be paid to not damaging aluminum forging products during and after the process.

BASIC FORGING OPERATIONS

Forward extrusion of rod [Fig. 4a], backward extrusion of can [Fig. 4b], simultaneous extrusion of can and can [Fig. 4c], can and rod or rod and rod and die forging [Fig. 4d] are recognized as typical basic aluminum forging operations. Actual forging will be done as combinations of them.

Forward Extrusion of Rod

Forward extrusion of rod is carried out as follows; billet which is kept in container [Fig. 4a 4], is forced by punch [Fig. 4a 1] to squeeze out from die orifice to form thinner rod. Reduction in area r is defined as

$$r = \left(\frac{d_0^2 - d_1^2}{d_0^2} \right) \times 100\% \quad (3)$$

Reduction in area can express the percentage magnitude of deformation of extrusion.

Herewith d_0 and d_1 denote diameters of billet and extruded rod [Fig. 5a]. A maximum peak of extruding force is observed at an early stage of punch displacement on the punch force versus displacement diagram [Fig. 6a]. After showing maximum peak of extruding force, it goes down gradually along with the punch displacement decreasing billet length and causing the decrease of frictional force between billet wall and container. Extruding pressure is affected by billet material, billet temperature, reduction in area, die angle 2α , frictional force on billet surfaces, extruding speed etc.

Backward Extrusion of Can

Backward extrusion of can is carried out as extruded material goes backward through the gap between container [Fig. 4b 4] and punch [Fig. 4b 1] as the punch is coming down into the billet supported by a container and counterpunch [Fig. 4b, 2]. Reduction in area r is defined as

$$r = \left(\frac{d_2^2}{d_0^2} \right) \times 100\% \quad (4)$$

Herewith d_0 and d_2 denote diameters of container and punch which coincide with the diameters of outer and inner diameters of can [Fig. 5b]. Punch force keeps rather flat in punch force and displacement diagram because increase of frictional force on a can's wall is not so serious. However it will be almost impossible to supply additional lubricant

Fig. 4 Basic forging operations, 1. Punch, 2. Backup punch, 3. Counter punch, 4. Container, 5. Die, 6. Upper die, 7. Lower die. (a) Forward extrusion of rod; (b) Backward extrusion of can; (c) Simultaneous extrusion of double cans; (d) Die forging

on punch top surface during operation from outside, so it is difficult to manufacture deep cans because of a shortage of lubricant on the punch surface. It is important to protect the punch from sitting in an eccentric position or buckling to manufacture deep cans. To manufacture very thin wall can, where the reduction in area is large, or to manufacture very thick wall can, where the reduction in area is small, a higher punch pressure is needed. For medium reduction in area $r = 40\text{--}60\%$ approximately, punch pressure takes minimum. At the end of punch displacement, punch force will increase suddenly [Fig. 6a] where billet length becomes short. For forging very short billets or flat plates, higher force is needed to withstand frictional force.

Simultaneous Extrusion

Extrusion with plural die orifices is called simultaneous extrusion. Control of the length of extruded parts is made by a suitable selection of sequence or die design. For the extrusion with two orifices, if they are extremely different in reduction in area, one extrusion is done in advance and almost no extrusion is made from the other orifice. To get suitable metal flow, sometimes a counter punch is fitted at the end of the extruded part to stop partial excess metal flow. To divide a deformation process into two or three stages is another method of getting sound metal flow. In the case of their being similar in reduction in area, the extruded part's length is adjustable by changing the die or punch design slightly.
